One-carbon (C1) substrates such as methane and methanol have been considered as the next-generation carbon source in industrial biotechnology with the characteristics of low cost, availability, and bioconvertibility. Recently, methanotrophic bacteria naturally capable of converting C1 substrates have drawn attractive attention for their promising applications in C1-based biomanufacturing for the production of chemicals or fuels. Although genetic tools have been explored for metabolically engineered methanotroph construction, there is still a lack of efficient methods for heterologous gene expression in methanotrophs. Here, a rapid and efficient electroporation method with a high transformation efficiency was developed for a robust methanotroph of Methylomonas buryatense 5GB1. Based on the homologous recombination and high transformation efficiency, gene deletion and heterologous gene expression can be simultaneously achieved by direct electroporation of PCR-generated linear DNA fragments. In this study, the influence of several key parameters (competent cell preparation, electroporation condition, recovery time, and antibiotic concentration) on the transformation efficiency was investigated for optimum conditions. The maximum electroporation efficiency of 719 ± 22.5 CFU/µg DNA was reached, which presents a 10-fold improvement. By employing this method, an engineered M. buryatense 5GB1 was constructed to biosynthesize isobutyraldehyde by replacing an endogenous fadE gene in the genome with a heterologous kivd gene. This study provides a potential and efficient strategy and method to facilitate the cell factory construction of methanotrophs.

Keywords: one-carbon substrate, site-specific chromosome expression, transformation efficiency, gene deletion, heterologous gene expression, methanotroph

INTRODUCTION

Methane, derived from natural gas and biogas, is the second most abundant greenhouse gas whose global warming potential is 25 times more than that of carbon dioxide (Fei et al., 2014; Pariatamby et al., 2015). Excessive methane emissions can not only cause a waste of carbon sources but also endanger the environment by causing the global warming effect (Bjorck et al., 2018;
Hu et al., 2020). Thus, it is urgent to seek a potential, green, and sustainable strategy for the efficient utilization of methane.

With the development of molecular biology, the bioconversion of methane into chemicals or biofuels by special industrial microbial catalysts has become a promising trend for its mitigation (Nguyen and Lee, 2020). Compared with chemical methods, the biological routes of methane utilization are relatively simple with the potential to directly activate methane at ambient temperature and atmospheric pressure (Conrado and Gonzalez, 2014). Methanotrophs are capable of utilizing methane as the sole energy and carbon source, which also constituted the main biocatalysts for the production of C1-based chemicals or biofuels (Hur et al., 2017; Su et al., 2017; Nguyen et al., 2018).

Notably, the methanotroph Methylomicrobium buryatense 5GB1, which can utilize one-carbon (C1) substrates (methane and methanol) for growth, has been studied extensively and in depth due to its promising characteristics for industrial application, including a fast growth rate, strong anti-contamination ability, a robust endogenous methane assimilation pathway, and the availability of genetic manipulation tools and bioreactor (Alexey et al., 2015; Yan et al., 2016; Fei et al., 2018). Currently, conjugation-based transformation plays an important role in achieving gene transfer and expression in M. buryatense 5GB1 (Puri et al., 2015), which usually requires a helper strain such as Escherichia coli S17-1 λpir to transfer DNA into a host due to the restriction–modification (R-M) system (Yan et al., 2016). Nevertheless, the time-consuming elimination of E. coli after conjugation limited the use of this method. Hence, to broaden the industrial application of M. buryatense 5GB1 in C1 substrate conversion, many gaps still need to be further solved, especially the development of efficient genetic manipulation methods for the metabolic engineering of methanotrophs.

Electroporation, as a direct gene transfer system, is widely used in various bacteria for DNA transfer (Itoh et al., 1994). It is reported that the key steps such as the preparation of competent cells, electroporation process, recovery process, and plating screening mainly affect the number of transformants and the transformation efficiency during the electroporation process (Fu et al., 2017; Morales-Ruiz et al., 2019). Moreover, compared with conjugation-based transformation methods, the electroporation method is relatively easy to perform for directly and efficiently inserting DNA fragments into specific sites of the genome to complete the heterologous gene expression. Because the R-M system of M. buryatense 5GB1 can be interfered by the plasmid transfer during electroporation, it could be an ideal choice to introduce linear DNA fragments by electroporation for efficiently achieving gene deletion and plasmid-free gene expression. In addition, the marker system Flp/FRT and a markerless system using the counterselectable marker sacB or pheS have been used for chromosomal modification in methanotrophs (Liu et al., 2021), but an available and efficient method to establishing a common site for completing heterologous gene expression in the genome of M. buryatense 5GB1 is still required.

This study aimed to develop a site-specific chromosome expression (SSCE) method with an efficient electroporation system for methanotrophs using an antibiotic-selected marker due to its stability (Yan et al., 2016). Since the deletion of beta-oxidation did not show a negative influence on the growth of M. buryatense 5GB1 (Demidenko et al., 2016), the position of the fadE gene on the chromosome was selected as a specific site. The key parameters of the gene manipulation method, such as the DNA concentration, cell density, methanol concentration, recovery time, field strength, and the antibiotic concentration, that affect the transformation efficiency of M. buryatense 5GB1 were investigated and optimized in this study. To demonstrate the feasibility of this novel electroporation-based method, the gene deletion and heterologous gene expression strategies in M. buryatense 5GB1 were established by artificially replacing the endogenous fadE gene with the heterologous kivd gene for isobutyraldehyde biosynthesis. Finally, the performances of the plasmid-based method and the SSCE method were analyzed and compared in order to evaluate the specific site of fadE for exogenous gene expression.

**MATERIALS AND METHODS**

**Strains, Plasmid, Culture, and Antibiotic Screening**

The strains and plasmids used in the study are listed in Table 1. Competent cells (E. coli DH5α) were cultured on Luria broth (LB) agar plates and M. buryatense 5GB1S were stocked on nitrate mineral salt (NMS) agar medium with 1% methanol. The mating plate (NMS2) consisted of 85% NMS and 15% LB agar culture media. The concentrations of the carbonate buffer and the phosphate buffer were individually adjusted to 5 and 200 mM, respectively, and the transformation efficiency during the electroporation was investigated and optimized in this study. To demonstrate the feasibility of this novel electroporation-based method, the gene deletion and heterologous gene expression strategies in M. buryatense 5GB1 were established by artificially replacing the endogenous fadE gene with the heterologous kivd gene for isobutyraldehyde biosynthesis. Finally, the performances of the plasmid-based method and the SSCE method were analyzed and compared in order to evaluate the specific site of fadE for exogenous gene expression.

**DNA Manipulation**

The plasmid pAWP89 was separated from E. coli DH5α with an AxyPrep Plasmid Miniprep Kit (Axygen, Suzhou, China) and linearized by NSPl (NEB, Beijing, China). The concentration of DNA was measured by the DS-11 spectrophotometer (DeNovix, Wilmington, DE, United States). The oligonucleotides used to amplify the DNA fragments are listed in Supplementary Table 1. The complex (DNA fragment) was obtained by overlap PCR. The fragments were retrieved using MonPure Gel and PCR Clean Kit (Monad Biotech, Wuhan, China). The transformants were identified by two oligonucleotides of the target gene, and a 2 × Rapid Taq Master Mix (Vazyme, Nanjing,
China) was used. The Ezup Column Bacteria Genomic DNA Purification Kit (Sangon Biotech Co., Shanghai, China) was used to extract genomic DNA.

**Electroporation Protocol**

Methylomicrobium buryatense 5GBIS was firstly cultured at 30°C with shaking until the optical density at 600-nm wavelength (OD600) reaches 2.0, checked with UV spectrophotometry (TU-1810, PERSEE, Beijing, China). Then, the cells in the logarithmic phase were collected and 50 ml of the bacterial solution was centrifuged to remove supernatants (5,000 × g, 10 min at 4°C), then cleaned three times with ice-cold water (autoclave sterilization, 121°C for 20 min). Finally, methanotroph competent cells were completely dissolved with 500 µl deionized water, and 50 µl of competent cells was mixed with 100, 200, 400, 600, 800, or 1,000 ng of DNA fragment. For the electroporation process, 1-mm-gap cuvettes were placed into the Gemini SC2 instrument (BTX, Holliston, MA, United States) to finish the electroporation process. After electroporation, 1 ml of fresh NMS was added to the cuvette, which was transferred into the 10 ml NMS medium in 250-ml serum bottles. Different concentrations of methanol (0.02–0.5%) were added to the resuscitation medium to culture the cells. The cells were collected and transferred into plates containing different concentrations of kanamycin after 3, 6, 9, 12, and 24 h of resuscitation. The plates were incubated for 4 days at 30°C for screening of transfectants. The cell density (1.0, 2.9, 4.9, 9.7, and 11 µg/ml) was determined using a UV spectrophotometer.

**Method for Recombinant Plasmid Transfer**

Escherichia coli DH5α, M. buryatense 5GBIS, and E. coli DH5α (PRK600) were involved in the conjugation process. NMS2 mating plates were prepared according to a previous literature (Puri et al., 2015). Firstly, we transferred the recombinant plasmid pHLZ66 into E. coli DH5α (donor bacteria). Secondly, one loop of M. buryatense 5GBIS was evenly coated in NMS2 mating plates (15% LB + 85% NMS) and cultured overnight at 30°C. Then, E. coli DH5α and PRK600 were cultured on LB medium overnight at 37°C. Equal volumes of E. coli DH5α and E. coli DH5α (PRK600) were evenly spread on NMS2 mating plates and cultured at 30°C for 2 days. One loop of mixed cells was transferred to a selective NMS plate with kanamycin (100 µg/ml) for the selection of transconjugants, which were then transferred into a new selective NMS plate.

**Isobutyraldehyde Detection**

The concentration of isobutyraldehyde was determined using Agilent Technologies 7890A GC System (Agilent Technologies, Santa Clara, CA, United States) with a DB-Wax column (30 m × 0.32 mm × 0.5 µm; Agilent Technologies) and a flame ionization detector. The flow rates of hydrogen, air, and nitrogen were 30, 400, and 25 ml/min, respectively. The oven temperature was held at 35°C for 5 min, then heated to 230°C at a rate of 12°C/min, and ending at 230°C. The retention time of isobutyraldehyde was 1.667 min. A standard curve was obtained.
RESULTS

Establishment of a Fast Electroporation Method for Endogenous Gene Deletion

Although it has been shown that DNA transfer can be achieved through electroporation into methanotrophs (Yan et al., 2016; Nguyen et al., 2018; Liu et al., 2021), optimum conditions of the electroporation system for *M. buryatense* 5GB1S are still needed to ensure a higher transformation efficiency of gene deletion before developing the SSCE method. After obtaining the *fadE* gene deletion complex (PCR product) for the construction of *M. buryatense* 5GB1SΔfadE by electroporation (Supplementary Figure 1), the influence of six different DNA concentrations on the number of transformants was firstly investigated. As can be seen in Figure 1A, the number of transformants was less than 20 at a DNA concentration of 100 ng, which increased to up to 30 at 200 ng, which is in good agreement with a previous report (Yekta et al., 2013). However, the number of transformants showed a plateau effect after using 400 ng DNA, which was finally selected for subsequent experiments.

The cell density can also affect the transformation efficiency, showing a positive relation in Figure 1B. At a cell density of 3.9 × 10^11 CFU/ml, the transformation efficiency increased to 14 times higher than that of 1.0 × 10^11 CFU/ml; the
highest transformation efficiency in *M. buryatense* 5GBlSΔ*fadE* of 491 CFU/µg DNA was achieved at a cell density of 9.7 × 10¹¹ CFU/ml, which can be considered as a statistically significant effect. These findings can be explained by the higher cell concentration indirectly promoting the efficiency of transformation by increasing the probability of binding with DNA. Nevertheless, when the cell density was 1.9 × 10¹² CFU/ml, the transformation efficiency was less than 100 CFU/µg DNA. Methanol, as an essential carbon source, was explored for cell recovery and growth after electroporation. As shown in Figure 1C, when the concentration of methanol added into NMS increased from 0.02 to 0.5%, the transformation efficiency was enhanced from less than 60 to up to 400 CFU/µg DNA. These results revealed that a higher methanol concentration is needed to improve the transformation efficiency by promoting the growth and reproduction of transformants. But it is worth noting that only a few transformants were observed with the concentration of 1%, which may be due to the inhibition effect of methanol.

In addition, studies have shown that the field strength and antibiotic concentration also affected the efficiency of transformation because a high field strength during electroporation is likely to destabilize the cell walls of Gram-positive bacteria and different antibiotic concentrations can affect the growth and reproduction of transformants (Dower et al., 1988; McIntyre and Harlander, 1989; Steele et al., 1994; Shimogawara et al., 1998; Min et al., 2018). However, our data showed that field strength of 12–25 kV/cm and antibiotic concentrations of 50–100 µg/ml did not provide significant improvements in the transformation efficiency of *M. buryatense* 5GBlS (data not shown). The process of recovery is a stage of cell growth, reproduction, damage repair, and resistance gene expression (Li et al., 2014). Therefore, a relatively long recovery benefits the rapid growth of cells and the successful recombination of exogenous DNA fragments into the genome. However, a satisfactory transformation efficiency can only be achieved with a recovery time of 12 h (Figure 1D). In the end, the electroporation conditions used for the SSCE method were as follows: cell density, OD₆₀₀ = 9.7 × 10¹¹ CFU/ml; field strength, 18 kV/cm; recovery time, 12 h; carbon source concentration, 0.5%; and kanamycin concentration, 100 µg/ml. Finally, the highest transformation efficiency for *fadE* gene deletion was 719 ± 22.5 CFU/µg DNA, which was 10 times more than that of the initial condition (66.25 CFU/µg DNA).

**Development of the SSCE Method for Heterologous Gene Expression**

To evaluate the SSCE method, *M. buryatense* 5GBlS was engineered for the biosynthesis of isobutyraldehyde, which is the key precursor of isobutanol applied as an attractive fuel substitute (Atsumi et al., 2010). The gene encoding alpha-ketoisovalerate decarboxylase (*KivD*) from *Lactococcus lactis*, which can catalyze 3-methyl-2-oxobutyric acid to isobutyraldehyde, was used as the heterologous gene, as shown in Figure 2A. Two strategies can be employed for the expression of the heterologous gene *kivd* in methanotrophs: a plasmid-based expression (Figure 2B) and
a chromosome-based homologous recombination (Figure 2C). Although the former has been applied in many model strains with better outcomes, the R-M system in methanotrophs results in a lower efficiency. Therefore, a modified chromosome-based method was developed to provide a fast and efficient system. As shown in Figure 3 and Supplementary Figure 2, the recombinant strain (M. buryatense 5GBISΔfadE:Km\(^r\):kivd) was constructed by replacing the specific site of the fadE gene in the genome with the exogenous DNA fragment of kivd and Km\(^r\). Furthermore, to verify the validity of the fadE gene site as an effective and specific site for heterologous gene expression, the pos5 gene, for regulating the reducing power level and promoting product accumulation from Saccharomyces cerevisiae coding for NADH kinase along with the Gm\(^r\) fragment, was also introduced into the fadE site, giving the recombinant strain of M. buryatense 5GBISΔfadE:Gm\(^r\)-pos5 successfully (Supplementary Figures 3–5).

To investigate the expression efficiency of the exogenous gene insertion at the fadE site, a plasmid-based recombinant (M. buryatense 5GBIS-pAWP89:kivd) was constructed for comparison. As shown in Figure 4, M. buryatense 5GBISΔfadE:Km\(^r\):kivd, with the best situation for growth, displayed the highest OD\(_{600}\) of 7.0, followed by OD\(_{600}\) = 6.0 for M. buryatense 5GBIS (wild type) and OD\(_{600}\) = 5.0 for M. buryatense 5GBIS-pAWP89:kivd. The biosynthesis of isobutyraldehyde was also validated in the recombinants and wild type. As shown in Table 2, it is clear that the wild-type strain could not accumulate isobutyraldehyde due to the lack of the kivd gene. Because of the successful overexpression of the heterologous kivd gene, the accumulation of isobutyraldehyde was obtained in both recombinants with a similar titer around 3.3 mg/L. Overall, the SSCE method with the fadE site was developed as a promising and plasmid-free strategy for heterologous gene expression with chromosome integration.

**DISCUSSION**

To obtain powerful cell factories, faster and more convenient genetic tools are essential. Electroporation-based transformation...
is a simple and efficient method for the genetic engineering modification of microorganisms, so improving the DNA transfer efficiency of electroporation is conducive to the rapid and efficient construction of engineered bacteria, which can be applied in industrial applications of methanotrophs. In *M. buryatense* 5GB1S, C1 substrates are taken up and bioconverted into ketoisovalerate, which is the main precursor for the synthesis of isobutyraldehyde (Matsuda et al., 2013; Miao et al., 2018).

To complete the heterologous gene expression, an efficient electroporation system based on *M. buryatense* 5GB1S was firstly optimized. Key factors including the cell density, methanol concentration, and recovery time were investigated based on previous reports (Puri et al., 2015; Yan et al., 2016; Nguyen et al., 2018; Liu et al., 2021). Therein, the cell density also showed a positive relation with the electroporation efficiency of *M. buryatense* 5GB1S, and this is consistent with previous reports (Holo and Nes, 1989; Shimogawara et al., 1998; Wu and Letchworth, 2004). For example, researchers have explored the influence of the DNA concentration on the transformation efficiency of fibroblasts and found that the transformation efficiency was increased by 17 times with the DNA concentration increasing fourfold (Yekta et al., 2013). Moreover, it was reported that the ability of electroporation to transfer DNA into cells was limited under a fixed cell concentration, and excess DNA remained inefficient (Hattermann and Stacey, 1990; Rittich and Španová, 1996). It is believed that a high substrate concentration will facilitate cell growth and improve efficiency. It has been reported that a high methanol concentration in the electroporation system could easily trigger cell lysis, resulting in low conversion efficiency (Yan et al., 2016). Consequently, similar findings were observed when the methanol concentration was 1.0%, providing a dramatically low efficiency. Furthermore, an appropriate recovery time is beneficial to the improvement of the transformation efficiency, which could severely affect the conversion efficiency due to blocking of the efficient entry of linear DNA into the cell and difficulty in the screening of transformants (Hattermann and Stacey, 1990; Yan et al., 2016). The longer recovery time in this study also showed lower efficiency mainly due to cell lysis (Yan et al., 2016).

The optimized SSCE method developed in this research showed unique advantages in gene deletion and heterologous gene expression in methanotrophs compared with the existing methods. A higher transformation frequency was observed when using PCR-generated fragments to delete the *glgA2* (0.7 kb) and *mmo* (0.83 kb) genes in methanotrophs through electroporation (Yan et al., 2016), which may be due to the shorter length of the selected genes compared with that of *fadE* (2.3 kb). Thus, the frequency of 71.9 ± 22.5 CFU/µg DNA obtained from this *fadE*-based SSCE was still high enough for most genetic manipulations, including gene deletion and heterologous gene expression in *M. buryatense* 5GB1S. Moreover, the antibiotic cassette used in the *fadE*-based SSCE method was less than 1 kb in comparison to the markerless counterselection cassettes *pheS* and *sacB* used in methanotrophs, which can facilitate the overlap step during PCR (Nguyen and Lee, 2020). Finally, the biosynthesis of isobutyraldehyde was conducted by heterologously expressing *kivd* in *M. buryatense* 5GB1S with deletion of the *fadE* gene. Favorably, better growth was achieved with a similar isobutyraldehyde titer from the SSCE method compared with the plasmid-based method because of the metabolic burden of the plasmid. Nevertheless, the yield of isobutyraldehyde on cell density from *M. buryatense* 5GB1S::*fadE::Km*:*kivd* (0.69 mg/L per OD_{600}) was lower than that of *M. buryatense* 5GB1S::pAWP89::*kivd* (0.89 mg/L per OD_{600}), which may be due to the higher copy number from a plasmid than a single copy of the inserted gene. Thus, optimization of the promoters or the ribosome-binding site (RBS) for this *fadE*-based SSCE method is required in future works in order to deliver a robust strategy for the genetic engineering of methanotrophs.

In this work, an efficient and rapid method was developed to delete the endogenous gene and complete the heterologous gene expression in *M. buryatense* 5GB1S simultaneously. The exogenous gene *kivd* was inserted into the genome of

![FIGURE 4](image-url) Growth performance of the wild-type (Methylomicrobium buryatense 5GB1S) and mutant strains for isobutyraldehyde biosynthesis.
M. buryatense 5GB1S (fadE), forming an isobutyraldehyde producer. Moreover, the fadE site could be used as an effective and specific site for the exogenous expression, with better growth due to the plasmid-free system. Overall, this study not only provides a bright idea for gene deletion and expression but also enriches the scope of genetic tools for methanotrophs, which promotes the application of methanotrophs in the utilization of C1 substrates.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding author/s.

AUTHOR CONTRIBUTIONS

QF and LH conceived and designed the work and provided conceptual advice with inputs from all authors. LH planned and performed the experiments and analyzed the data. LH, SG, and QF wrote and revised the manuscript. TZ and JX helped to complete the work. SG and XY provided conceptual advice.
