ABSTRACT

The HDO/H₂O abundance ratio is thought to be a key diagnostic for the evolution of water during the star and planet formation process and thus for its origin on Earth. We here present millimeter-wavelength high angular resolution observations of the deeply embedded protostar NGC 1333-IRAS4B from the Submillimeter Array targeting the 3_{12}–2_{21} transition of HDO at 225.6 GHz (E_u = 170 K). We do not (or only very tentatively) detect the HDO line toward the central protostar, contrasting the previous prominent detection of a line from another water isotopologue, H₂^{18}O, with similar excitation properties using the IRAM Plateau de Bure Interferometer. The non-detection of the HDO line provides a direct, model-independent, upper limit to the HDO/H₂O abundance ratio of 6×10^{-4} (3σ) in the warm gas associated with the central protostar. This upper limit suggests that the HDO/H₂O abundance ratio is not significantly enhanced in the inner ≈50 AU around the protostar relative to what is seen in comets and Earth’s oceans and does not support previous suggestions of a generally enhanced HDO/H₂O ratio in these systems.

Key words: astrochemistry – ISM: abundances – ISM: individual objects (NGC 1333-IRAS4B) – protoplanetary disks – stars: formation

1. INTRODUCTION

One of the key questions concerning the formation of planets, and Earth in particular, is how water has evolved on its way from collapsing molecular cloud cores to protoplanetary disks and eventually Earth’s oceans. In cold and quiescent regions, the gas-phase water abundance is low, only 10^{-9} to 10^{-8} or less (e.g., Bergin & Snell 2002; Caselli et al. 2010), but in regions forming low-mass protostars with intense heating or active shocks, its abundance can reach 10^{-4} with respect to H₂—comparable to or higher than that of CO (e.g., Kristensen et al. 2010). Thus, in the earliest prestellar stages and in large parts of the dense envelopes around low-mass protostars, H₂O is largely frozen out and is the dominant constituent of the icy mantles of dust grains. It is thought that the amount of deuterated relative to non-deuterated water is established in these grain mantles. Observations show that this abundance ratio is enhanced in comets (≈(3–4)×10^{-4}; e.g., Bockelée-Morvan et al. 1998; Villanueva et al. 2009) and Earth’s oceans (≈1.5×10^{-4}; e.g., Robert et al. 2000, and references therein) relative to primordial D/H ratio in the protosolar nebula (≈1.5×10^{-5}; Geiss & Gloeckler 1998; Linsky 2003). Determining when and where this ratio is established is thus a potentially important way to trace the evolution of water in the different stages of star formation. In particular, it might help determine what fraction of water was brought to Earth at later times through cometary impacts compared to being accreted during the formation of the planet itself (e.g., Morbidelli et al. 2000; Raymond et al. 2004) and whether water undergoes significant processing in warm regions of protostellar envelopes or disks before reaching newly formed planets.

Previous attempts at measuring the ratio of HDO and H₂O in low-mass protostars have had mixed success. Direct attempts to detect HDO in the solid phase at infrared wavelengths have provided upper limits of [HDO]/[H₂O] varying from 0.005 to 0.02 in a sample of protostars (Parise et al. 2003), which are not strong constraints compared to the two orders of magnitude lower abundance ratios observed in, e.g., the cometary systems. Measurements at (sub)millimeter wavelengths could potentially be sensitive to lower abundances of HDO in the gas phase in regions where the ices have evaporated off the dust grains and thus trace their compositions indirectly, but such measurements are complicated due to the achievable angular resolution using single-dish radio telescopes and have led to discrepant results. As an example, Stark et al. (2004) and Parise et al. (2005) analyzed the HDO emission toward the deeply embedded protostar, IRAS 16293-2422, compared to previous Infrared Space Observatory (ISO) and Submillimeter Wave Astronomy Satellite (SWAS) observations of non-deuterated H₂O. Both presented detailed models for the HDO abundance structure with significantly different results: Parise et al. found evidence for a drop in the [HDO]/[H₂O] ratio from 0.03 in the hot gas in the inner envelope (i.e., significantly enhanced above the comet values) to <0.002 in the cold gas on larger scales, whereas Stark et al. in contrast found that the abundance of HDO was best described as being constant throughout the envelope and with an [HDO]/[H₂O] ratio of 2×10^{-4}, comparable to the comet value, in the part of the envelope with T > 14 K. Part of this discrepancy may arise due to the complexities in comparisons between ground-based single-dish observations of HDO and space-based observations of H₂O probing significantly different spatial scales, and lines excited in different regions of the protostellar environment.

Our detection of thermal H^{18}O emission toward the deeply embedded Class 0 low-mass protostar, NGC 1333-IRAS4B (d = 250 pc), with the IRAM Plateau de Bure Interferometer (Jørgensen & van Dishoeck 2010) makes it possible to revisit the discussion of the origin of water on Earth, namely, where the relative abundances of deuterated and non-deuterated are established. In this Letter, we present a search for the 3_{12}–2_{21} transition of the HDO isotopologue at high angular resolution (2.5″–3″; corresponding to 625–700 AU) using the
Submillimeter Array (SMA). This transition is close in energy to the H$_2$O $3\rightarrow 2$ transition at 235.0 to 237.0 GHz (upper sideband, USB). The source was observed in the compact configuration of the SMA, which at the time of observations had seven antennae operational providing baselines ranging from 7 to 60 kλ.

The data were calibrated using the SMA version of the MIR package and imaged using Miriad. The calibration followed the standard approach: the absolute flux calibration was established through observations of Uranus, the bandpass by observations of the strong quasar 3c454.3, and the complex gains by regular observations of the nearby strong quasars 3c84 and 3c111 (approximately 5.2 and 4.7 Jy at 1.33 mm, respectively). Integrations with clearly deviating amplitudes and/or phases were flagged and the continuum was subtracted prior to Fourier transformation of the line data. With natural weighting the resulting beam size is 3″1 × 2″5 at a position angle of −66°; the field of view is 52″ (HPBW) at 1.33 mm. The resulting rms noise level is 58 mJy beam$^{-1}$ channel$^{-1}$ for the line data with the 0.27 km s$^{-1}$ spectral resolution using natural weighting.

3. RESULTS

Both IRAS4B and its nearby companion IRAS4B′ are clearly detected in the continuum data. Table 1 lists the results of elliptical Gaussian fits to the two sources: both are resolved with fluxes in agreement with the results from Jørgensen et al. (2007) within the absolute flux calibration uncertainty of 20%.

Figure 1 shows the spectrum from 1 GHz of the LSB of IRAS4B labeling a number of lines with peaks at the 3σ level or above. The H$_2$CO $3\rightarrow 2$, transition at 225.698 GHz is clearly dominant as expected, with lines of complex organic molecules as well as OC$_3$S and C$_2$H$_5$ also detected. Most importantly the identification of the multiple lines centered at the continuum position confirms both the pointing of the observations as well as the calibration of the frequency axes of the spectra.

Figure 2 shows a zoom-in on the spectrum in the high resolution chunk around the HDO $3\rightarrow 2$ transition. No clear line is seen at the systemic velocity of 7.0 km s$^{-1}$ of the H$_2$O $3\rightarrow 2$ transition (Jørgensen & van Dishoeck 2010) and other species surveyed at high angular resolution with the SMA (Jørgensen et al. 2007)—although a tentative detection may be present at the ≈3σ level (integrated intensity). This is confirmed by the integrated intensity map (Figure 2, right), which shows a 3σ contour close to the location of the continuum peak. Statistically speaking it cannot be counted a firm detection, however, and we therefore treat it as an upper limit in the following.

4. DISCUSSION: AN UPPER LIMIT ON THE RATIO OF THE HDO/H$_2$O ABUNDANCES IN THE INNER 50 AU REGIONS OF A LOW-MASS PROTOSTAR

The 3σ upper limit on the integrated line intensity (or approximate strength of the tentative detection) of the HDO transition can be estimated as $\sigma_{3\sigma} = 3\sqrt{\Delta \nu \delta \nu} \sigma_{\text{rms}} \approx 0.13$ Jy km s$^{-1}$, assuming a line width to zero intensity of 2 km s$^{-1}$ as found for the H$_2$O transition. The column density of HDO corresponding...
to this intensity can be estimated under the same assumptions as for the H$_2$O transition and can thus be compared directly, assuming that the emission is optically thin and uniform over the extent of the H$_2$O emission (thus diluted in our SMA beam).

Using the non-LTE escape probability code Radex (van der Tak et al. 2007), we calculated column densities corresponding to the observed line intensities for different values of the kinetic temperature and H$_2$ density. Figure 3 shows the derived HDO/H$_2$O abundance ratio as function of kinetic temperature and density, respectively. In the range from about 100 to 1000 K and for densities larger than about 10$^9$ cm$^{-3}$ (the density expected in the inner envelope or disk) the derived [HDO]/[H$_2$O] 3σ upper limit on the abundance ratio varies from about 2 × 10$^{-4}$ to 6 × 10$^{-4}$ assuming an ortho–para ratio for H$_2$O of 3:1 and a $^{16}$O/$^{18}$O ratio of 560. If the tentative detection would be confirmed by more sensitive observations, the implied HDO/H$_2$ abundance ratio would suggest a level of deuteration comparable to what is observed in cometary ices. The Radex calculations show that the inferred abundance ratio can vary from about 1 × 10$^{-4}$ to 1 × 10$^{-3}$ if the excitation temperatures are allowed to differ for the two species and vary between 100 and 1000 K, covering a wider range of physical parameters. The beauty of the above result is that it does not depend on the assumed physical structure of the source, and in particular, whether the origin of the observed water is due to shocks or ice desorption in either envelope or disk material.

One caveat is that the H$_2$O transition could be masing as is the case for the same transition of main H$_2$O isotopologue at 183 GHz (e.g., Cernicharo et al. 1994). In that scenario the H$_2$O column density would be overestimated and thus the [HDO]/[H$_2$O] ratio underestimated. A few observational facts argue against this being a major issue for the H$_2$O transition toward IRAS4B, though: the width of the H$_2$O transition (2 km s$^{-1}$ to zero-intensity) is very close to those of the other species (SO$_2$, C$_2$H$_5$CN, and CH$_3$OCH$_3$) observed in the central beam toward the continuum peak of IRAS4B. This trend is further strengthened with detections of the H$_2$O transition toward two other embedded protostars (M. Persson et al. 2011, in preparation): the lines of H$_2$O, SO$_2$, and the organic species in these three sources show smaller species-to-species variations than source-to-source variations both in terms of their line widths and strengths. This suggests that the origin of the emission is the same in each of the individual sources and therefore that H$_2$O emission is dominated by the thermal component and at most weakly masing. Finally, previously detected H$_2$O water masers at 22 GHz in IRAS4B are clearly offset from the systemic velocity (Marvel et al. 2008; Desmurs et al. 2009) and their motions in the outflow propagation direction are perpendicular to the tentative velocity gradient observed in the H$_2$O transition. Thus, the H$_2$O line is at least not masing in the gas where the 22 GHz H$_2$O maser has its origin.

The derived upper limit to the HDO/H$_2$O abundance ratio does not support the suggestion by Ceccarelli et al. (2005) and Parise et al. (2005) that the HDO/H$_2$O abundance ratio is abnormally high in low-mass protostars or their disks compared to the abundance ratios found in comets, Earth’s oceans, or in high-mass hot core regions (e.g., Jacq et al. 1990; Gensheimer et al. 1996; van der Tak et al. 2006). In agreement with Stark et al. (2004), the results favor a scenario in which the HDO/H$_2$O ratio is conserved during the star formation process. There is thus also no need to invoke the formation of water in the gas phase.
in a longer-lived early stage of low-mass protostars where the deuterium fractionation is too high to explain the constraints on the HDO/H$_2$O abundance ratio. The conclusion that the HDO/H$_2$O abundance ratio is determined in the cold core phase and is conserved throughout the formation of low-mass stars and icy solar-system bodies is consistent with the evolutionary models of Visser et al. (2009) that show that the bulk of the ice remains in solid form during infall and disk formation. It is possible that the physical mechanisms for the origin of the warm gas in NGC 1333–IRAS4B and IRAS 16293–2422 differ: the latter source shows a complex structure with multiple organic species peaking at different locations (e.g., Kuan et al. 2004; Bisschop et al. 2008) and likely interaction with the protostellar outflow on small scales (Chandler et al. 2005). SMA observations of that source (J. K. Jørgensen et al. 2011, in preparation) suggest that this complex interplay could also have an impact on the line emission for the HDO isotopologue underlining the need for high angular resolution observations.

In any case, these observations show the great potential offered by high angular resolution submillimeter (interferometric) observations, even from the ground, for tracing the origin and evolution of water vapor during the evolution of young stars. An important step forward would be to spatially resolve both the emission profiles of HDO and H$_2$O in protostars in different evolutionary stages to reveal any temporal or spatial variations of their abundance ratios. More sensitive observations with the Plateau de Bure as well as future observations with the Atacama Large Millimeter Array in Band 5 will make this possible and thereby make an important contribution toward answering the questions about the origin of water in planetary systems.

We are grateful to Tim van Kempen for helpful comments about the manuscript. Research at Centre for Star and Planet Formation is funded by the Danish National Research Foundation and the University of Copenhagen’s programme of excellence. Research in astrochemistry in Leiden is supported by a Spinoza Grant from the Netherlands Organization for Scientific Research (NWO) and a NOVA grant. This Letter is based on data from the Submillimeter Array: the Submillimeter Array is a joint project between the Smithsonian Astrophysical Observatory and the Academia Sinica Institute of Astronomy and Astrophysics and is funded by the Smithsonian Institution and the Academia Sinica.
