SUMMARY

Lithium selenium (Li-Se) batteries have attracted increasing interest for its high theoretical volumetric capacities up to 3253 Ah L⁻¹. However, current studies are largely limited to electrodes with rather low mass loading and low areal capacity, resulting low volumetric performance. Herein, we report a design of covalent selenium embedded in hierarchical nitrogen doped carbon nanofibers (CSe@HNCNFs) for ultra-high areal capacity Li-Se batteries. The CSe@HNCNFs provide excellent ion and electron transport performance, while effectively retards polyselenides diffusion during cycling. We show the Li-Se battery with mass loading of 1.87 mg cm⁻² displays a specific capacity of 762 mAh g⁻¹ after 2500 cycles, with almost no capacity fading. Furthermore, by increasing the mass loading to 37.31 mg cm⁻², ultra-high areal capacities of 7.30 mAh cm⁻² is achieved, which greatly exceeds those reported previously for Li-Se batteries.

Keywords: Li-Se batteries, covalent selenium, mass loading, areal capacity.
INTRODUCTION

Lithium ion batteries (LIBs) represent the primary energy storage technology that is critical for mobile electronics and electric vehicles (Sun et al., 2019; Sun et al., 2017; Liang et al., 2019). There is considerable interest in developing newer generation of energy storage devices that may deliver higher energy density, higher power density and longer cycle life than the current state-of-the-art LIBs. Lithium-sulfur (Li-S) batteries have received significant recent attention for their high theoretical energy density, high earth abundance, low cost and eco-friendliness (Cheng et al., 2018). Unfortunately, there are several inherent obstacles towards the practical application of Li-S batteries including low utilization ratio of sulfur, serious polysulfide shuttling effect and rapid capacity decay (Zhang et al., 2010; Tao et al., 2016; Park et al., 2015).

Li-Se batteries are considered as an interesting alternative to Li-S batteries because of similar chemical properties and theoretical volumetric capacity ($\text{Li}_2\text{Se}, 3253 \text{ Ah L}^{-1}$), higher electronic conductivity ($10^{-3} \text{ S m}^{-1}$), higher active material utilization and better rate capability (Luo et al., 2013). However, Li-Se batteries also undergo serious polyselenides (PSes, $\text{Li}_2\text{Se}_x, 4 \leq x \leq 8$) “shuttle effect”, thus leading to irreversible capacity loss (Abouimrane et al., 2012; Yang et al., 2013; Han et al., 2014; Luo et al., 2014). To overcome this challenge, a variety of carbon materials with loading active selenium have been reported (Qu et al., 2015; Song et al., 2015), including porous carbon spheres (Luo et al., 2013; Li et al., 2014), carbon nanotubes (Han et al., 2014; He et al., 2016) and so on, to trap PSes in pores and improve the electrochemical properties of Li-Se batteries (Ding et al., 2018). However, the current studies are largely limited to electrodes with rather low mass loading and low areal capacity, cannot satisfy the practical application.

To simultaneously achieve high power density and high energy density requires ideal electrode structures that can rapidly release enough charges (electrons and ions) within a given charge-discharge period, as well as can store abundant charges (such as lithium ions). This situation can be easily achieved under relatively thin films and
nano-scale materials electrode with low mass loading (<1 mg cm\(^{-2}\)) (Sun et al., 2015; Li et al., 2014; Li et al., 2015). Nevertheless, as thickness of the electrode increases, the limitation of ion diffusion becomes more serious, so it is difficult to reach the mass loading of industrial application (~10 mg cm\(^{-2}\)) (Singh et al., 2015). Enhancing areal capacity by increasing areal mass loading may seem straightforward. There also has been limited success so far due to some key challenges related to the intrinsic nature of Se/C composites (Abouimrane et al., 2012; Yang et al., 2013; Han et al., 2014; Luo et al., 2014). Up to now, the reported highest areal mass loading and areal capacity of Li-Se batteries are 6.64 mg cm\(^{-2}\) and 4.12 mAh cm\(^{-2}\), respectively (Ding et al., 2018).

In addition, due to the presence of other passive components such as current collectors, binders and conductive additives in the practical device, the excellent electrochemical performance of the Li-Se batteries may be reduced rapidly (Gogotsi et al., 2011). Therefore, it has been rarely reported that mass loading or areal capacities of energy storage devices is higher than that of currently available LIBs (Kalimuthu et al., 2017; Yang et al., 2013; Zhang et al., 2018; Zeng et al., 2015; Hong et al., 2018).

Here, we reported an architecture of covalent selenium embedded in hierarchical N-doped carbon nanofibers (CSe@HNCNFs) as flexible, free-standing and binder-free cathode for Li-Se batteries. The CSe@HNCNFs with hierarchically porous structure (micro/meso/macro-pores and nano-channels), high-content nitrogen doping and robust covalent bonds (Se-O and Se-C) can not only facilitate the rapid transport of ions and electrons throughout the entire electrode architecture, but also effectively anchor PSes diffusion and affords built-in void space to tolerate the volume change during cycling. Thus, excellent electrochemical performance was achieved under different mass loading (from 1.52 to 37.31 mg cm\(^{-2}\)). When mass loading was 1.52 mg cm\(^{-2}\), a high specific capacity of 412 mAh g\(^{-1}\) (normalized by the mass of Se) could be maintained under current density of 40.61 mA cm\(^{-2}\). Moreover, the composite cathode with high mass loading up to 37.31 mg cm\(^{-2}\) delivered a high areal capacity of 7.30 mAh cm\(^{-2}\) (the highest areal capacity among all the Li-Se
batteries) at a current density of 0.83 mA cm$^{-2}$. This work represents a critical step toward capturing high areal capacity Li-Se batteries to meet practical devices.

**RESULTS**

**Preparation and Structure of CSe@HNCNFs Composite**

In the specific synthesis process, polyacrylonitrile (PAN) and polymethylmethacrylate (PMMA) were used as carbon source and pore-forming agent, respectively. PAN/PMMA nanofiber film was obtained by electrospinning, and then pre-oxidized at 280 °C. During the pre-oxidized process, the PMMA was decomposed, leading to formation of nano-channel and porous structure within the nanofiber film. After that, selenium powder sprinkled on pre-oxidized PAN fabric was encapsulated in a vacuum quartz bottle, and then annealed in a tubular furnace (Figure S1). It is worth noting that it is much easier to form covalent bonds with selenium vapor during annealing process due to a large number of unsaturated bonds of the pre-oxidized PAN and high reactivity of selenium at high temperature (Liu et al., 2017; Yang et al., 2018). Thus, the CSe@HNCNFs with hierarchically porous structure (micro/meso/macro-pores and nano-channels), and robust covalent bonds were obtained through the unique synthetic strategy.

The CSe@HNCNFs film with strong mechanical robustness and flexibility was cut into a 12 mm disc, and directly used as cathode for Li-Se batteries (Figure 1a). Scanning electron microscopy (SEM) images in Figure 1b and c show that uniform fibers in CSe@HNCNFs composite with diameter around 300 nm and smooth surface interwoven to form a good conductive networks, therefore guaranteeing fast electron conduction. As displayed in Figure S2, the CSe@HNCNFs show similar morphology with pure HNCNFs. As seen from side-view SEM image of a single fiber in Figure 1c, a hierarchically porous structure can be clearly observed, corresponding to transmission electron microscopy (TEM) images of CSe@HNCNFs (Figure 1d and e). The CSe@HNCNFs with hierarchically porous structure can not only accelerate
penetration of electrolyte, but also buffer volume expansion during charge-discharge process. Besides, high-resolution transmission electron microscopy (HRTEM) image and corresponding FFT pattern in Figure 1f indicate the selenium in the CSe@HNCNFs is amorphous state. As presented in Figure 1g-d, elemental mappings of CSe@HNCNFs suggest that the C, O, N, and Se are homogeneously distributed in CSe@HNCNFs.

The microstructure of the as-prepared materials was further analyzed by X-ray diffraction (XRD). Figure 2a displays that diffraction pattern of pure selenium exhibits an equilibrium trigonal crystal system P3121. The typical peaks of Se are obviously absent in CSe@HNCNFs and HNCNFs patterns, also suggesting a highly scattered amorphous state of selenium, leading to high utilization rate during the process of electrochemical (Li et al., 2015). The peaks of carbon at about 24° and 43° in XRD patterns of the CSe@HNCNFs shift to the left compared with that of HNCNFs due to increased lattice constant caused by selenium doping in CSe@HNCNFs. As shown in Figure 2b, two characteristic peaks located at 1340 and 1580 cm\(^{-1}\) in CSe@HNCNFs and HNCNFs patterns correspond to the disordered carbon (I\(_D\)) and the ordered graphite lattice (I\(_G\)), respectively. The I\(_D\)/I\(_G\) of CSe@HNCNFs and HNCNFs showed almost the same ratio, indicating that the addition of selenium can hardly affect defect or disorder degree of HNCNFs. Since the Raman spectrum collect signals from the material surface, no obvious Raman peak of the pure selenium was found in the CSe@HNCNFs composite, which further proves the perfect expansion of selenium into HNCNFs (Li et al., 2015). X-ray photoelectron spectroscopy (XPS) was used to study the chemical composition of CSe@HNCNFs. Figure 2c shows pronounced O 1s, N 1s, C 1s, Se 3s, Se 3p and Se 3d peaks at about 533.4, 400.7, 284.8, 229.6, 161.6 and 55.6 eV, respectively. A main peak of 284.8 eV in the high resolution C 1s spectrum in Figure 2d can be divided into four kinds of peaks at 284.8, 286.7, 288.5 and 291.6 eV, corresponding to the C=C/C-C, C-N/C-O, C=O and C=O, respectively (Wang et al., 2019; Li et al., 2016). Figure 2e presents Se 3d spectra of pristine Se and CSe@HNCNFs with the 3d\(_{5/2}\) and 3d\(_{3/2}\)
peaks located at 56.06 and 55.20 eV, respectively. The spin orbitals are divided at 0.86 eV, while the 3d\textsubscript{5/2} and 3d\textsubscript{3/2} peaks of Se transfer to higher binding energies in CSe@HNCNFs compared with the 3d\textsubscript{5/2} and 3d\textsubscript{3/2} peaks of pure Se at 56.06 and 55.20 eV, respectively (Luo et al., 2013; Zhang et al., 2014). This shift is due to change in the density of selenium's electron cloud, indicating selenium formed bonds with other atoms (C and O) in the composite (Hong et al., 2018; Xin et al., 2016; Babu et al., 2007; Luo et al., 2015). Similarly, a wide peak of Se 3d with low strength at about 58.50 eV is due to the forming of Se-O or Se-C (Li et al., 2015). In addition, the N 1s spectra (Figure 2f) of CSe@HNCNFs shows the presence of graphite N (400.1 eV), pyrrolic N (399.2 eV) and pyridine N (398.2 eV) (Zhang et al., 2019; Delamar et al., 1992). The elemental contents of N in CSe@HNCNFs is as high as 12.66%. The N-doping can greatly improve the conductivity of this composite and thus improve the rate performance of the electrode (Ania et al., 2007; Biniak et al., 1997; Jiang et al., 2015). Thermogravimetric (TG) profiles were used to study weight ratio of selenium in the composite. As shown in Figure 2g, The weight loss of CSe@HNCNFs can be divided into two scopes, including a rapid weight loss scope between 280 and 520 °C, and a slow weight loss scope over 520 °C. The rapid and slow weight loss scopes are attributed to the different breakdown temperature of the Se-Se and the Se-C (Se-O) bonds, respectively (Zhang, 2014). Thus, the content of selenium in the carbon matrix is determined to be about 33% and the maximum selenium loading corresponding to the area of the independent electrode is determined to be 12.31 mg cm\textsuperscript{-2}. After Se loading in HNCNFs, specific surface areas of HNCNFs decreases from 19.4 to 13.7 m\textsuperscript{2} g\textsuperscript{-1} (Figure 2h), and pore-size distribution of microporous region (<2 nm) and mesoporous region (2-50 nm) decreases significantly (Figure 2i) due to the permeation of Se in the hierarchical structure of HNCNFs matrix.

**Electrochemical Evaluation of the CSe@HNCNFs Electrodes**

To explore electrochemical performance of CSe@HNCNFs cathode, 2032-type coin cell were assembled with lithium metal as anode and CSe@HNCNFs film as cathode.
Figure 3a and b show cyclic voltammograms (CV) and charge-discharge curves, respectively. During the first discharge cycle, two obvious cathode peaks at 1.52 and 1.27 V, indicate that the conversion from Se to Li$_2$Se experienced two-step reactions (Se $\rightarrow$ Li$_2$Se$_x$ $\rightarrow$ Li$_2$Se, $x \geq 4$) (Luo et al., 2013; Yang et al., 2013; Xin et al., 2012). However, only one peak appears in the cathode segment in the following cycles, which can be ascribed to the conversion of Se to Li$_2$Se. This is very owing to the irreversible reduction peak (1.52 V) which only appears in the first cycle and disappears in the follow cycles. The irreversible reduction peak (1.52 V) corresponds to the process of trace amount of cyclic Se$_8$ in nano-channels or on the surface of hierarchically porous nanofibers forming soluble polyselenides, Li$_2$Se$_x$ ($x \geq 4$) and shuttling into the electrolyte (Yang et al., 2013). It worth noting that the remaining Se exist as an amorphous state with only conversion reaction of Se to Li$_2$Se during the follow discharge process, indicating only one peak appears in the cathode segment in the following cycles (Yang et al., 2013; Li et al., 2014). As the cycle continues, the peak moves to high voltage, and overlaps from the fourth cycle. In the charge cycle, only one anode peak at around 2.0 V indicates only one-step reversible transformation from Li$_2$Se to Se. Consistent with CV results, there is only one platform from the second charge-discharge curve. After the first three cycles, the charge-discharge curves almost overlap, implying a highly reversible electrochemical reaction and an excellent cycling stability. In Figure 3b, the cell exhibits a low initial Coulomb efficiency (ICE), which is attributed to the following two reasons. First, the pure HNCNFs electrodes displaying low Coulombic efficiency at same current density, similar to previous report, is one of the reasons for the extremely low ICE (Yang et al., 2013). Second, the formation of an irreversible solid electrolyte interface (SEI) on the surface of anode would also cause low initial Coulombic efficiency (Luo et al., 2013).

Figure 3c is the cycling performance of CSe@HNCNFs electrode under current rate (C-rate) of 1 and 10 C (1 C =675 mA g$^{-1}$). It should be noted that the N-doped carbon host provides negligible specific capacities of 49.5 and 21.1 mAh g$^{-1}$ at 0.1 and 1 A g$^{-1}$, respectively (Figure S3). When the circulating current rates are 1 and 10 C, specific capacities of 762 and 465 mAh g$^{-1}$ are obtained after 2500 and 1100 cycles,
respectively, with almost no attenuation in capacity. Coulombic efficiency reaches more than 99.5% since the fifth cycle, indicating an outstanding electrochemical reversibility of the CSe@HNCNFs electrode. Moreover, the morphology, composition and chemical state of CSe@HNCNFs composite are shown as Figure S4 after cycling. The morphology and composition display almost no change compared with that before cycling (Figure S4a, b and c). The XPS investigations in Figure S4d, e and f show that high resolution C 1s, Se 3d spectra and N 1s spectra suggest almost same chemical state of CSe@HNCNFs electrode before and after cycling (Figure 2d, e and f). In addition, the proportion of C=O, Se-C and Se-O bonds increased after cycling, which was attributed to electrolyte decomposition and dissolution of polyselenium compounds. Figure 3c exhibits a continuous rise of the reversible capacity during the first 300 cycles, which may be ascribed to the hysteresis of electrolyte infiltrating in the hierarchically porous matrix and the reduced internal impedance (Figure S5). Meanwhile, we also conducted a series of long cycling test of CSe@HNCNFs electrodes with different mass loading at the C-rate of 1 C (Figure 3d). When the mass loads are 3.99, 5.27 and 7.00 mg cm\(^{-2}\), high specific capacities of 740.5, 717.8 and 702.8 mAh g\(^{-1}\) can be obtained even after 870, 520 and 350 cycles, respectively. Moreover, the CSe@HNCNFs electrode with a high mass loading of 14.04 mg cm\(^{-2}\) shows a high specific capacity of 582 mAh g\(^{-1}\). In addition, a series of long cycling test of CSe@HNCNFs electrodes are conducted at different C-rates with mass loading of 1.79 mg cm\(^{-2}\) (Figure S6). Apparently, the CSe@HNCNFs electrode demonstrates superior cyclic stability at different mass loading. On one hand, the CSe@HNCNFs electrode with hierarchically porous structure can effectively buffer volume change of Se and offer outstanding ion and electron transport performance. On the other hand, the CSe@HNCNFs with the amorphous selenium bonding tightly with the HNCNFs host through Se-O or Se-C and C-O bonds can immobilize PSes and prevent the active selenium transferring from the electrode to the electrolyte, thus improving the cycle stability of Li-Se battery (Li et al., 2015). We believe the covalent bonds coupled with the hierarchically porous N-doped host can be also extended to lithium-sulfur batteries (Zhang, 2014; Talapaneni et al., 2016).
Charge and discharge curves of CSe@HNCNFs electrode in Figure 4a exhibits no significant voltage drop and capacity loss with the increase of mass loading. This may be attributed to the low internal resistance and outstanding structural stability of CSe@HNCNFs electrode. Figure 4b displays charge-discharge profiles of CSe@HNCNFs electrode with a mass loading of 1.52 mg cm$^{-2}$ at different current rates. When the rates are 0.2, 0.5, 1, 2, 5, 10, 20 and 50 C, the corresponding specific capacities are 773.4, 726.2, 699.4, 658.7, 601.6, 547.6, 489.4 and 414 mAh g$^{-1}$, respectively. Even if the current density increases 250 times, the specific capacity maintenance rate is still as high as 54% compared with that at the current density of 0.2 C. Figure 4c is charge-discharge curves of CSe@HNCNFs electrode with ultra-high mass loading level of about 27.12 mg cm$^{-2}$ at different C-rates. The reversible capacity of the CSe@HNCNFs electrode is 699 mAh g$^{-1}$ at current rate of 0.1 C. When the rate increases to 0.2, 0.5 and 1 C, the corresponding specific capacities are as high as 680.4, 636.8 and 334.8 mAh g$^{-1}$, respectively. Figure 4d is rate performance under different mass loadings. The CSe@HNCNFs electrode with various mass loadings displays unconspicuous capacity fading at C-rates of 0.2, 0.5, 1, 2 and 5 C, displaying an excellent electrochemical reversibility. Particularly noteworthy is that the CSe@HNCNFs with a mass loading of 1.52 and 3.63 mg cm$^{-2}$ deliver high specific capacity of 414.0 and 150.7 mAh g$^{-1}$ at ultrahigh current rate of 50 C. The CSe@HNCNFs electrode with various mass loadings can also deliver high specific reversible capacity after the C-rate returns to 1, 0.5 and 0.2 C. Moreover, Figure 4e shows capacities versus cycle number of CSe@HNCNFs electrode with ultrahigh mass loading of 27.12 mg cm$^{-2}$ at various charge-discharge C-rates ranging from 0.1 to 2 C. The retention rate of specific capacity can still reach 42% at high current density of 6.07 mA cm$^{-2}$ (1 C). When the current density back to 1.21 mA cm$^{-2}$ (0.2 C), the reversible capacity can be maintained at 6.26 mAh cm$^{-2}$ ($\approx$700 mAh g$^{-1}$), indicating an outstanding tolerance of CSe@HNCNFs electrode with ultra-high mass loading to the rapid dynamics of Li-Se battery. In order to increase the mass loading of Se to make it competitive, we also measured the electrochemical performance of Li-Se batteries under higher mass loading (37.31 mg cm$^{-2}$) of the CSe@HNCNFs
electrode. As shown in Figure S7, the CSe@HNCNFs electrode with an ultra-high mass loading of 37.31 mg cm\(^{-2}\) can still show good electrochemical performance under different current rates. The ultra-high mass loading of CSe@HNCNFs electrode enabled the Li-Se battery to display extremely high areal capacity (7.30 mAh cm\(^{-2}\)). Simultaneously, the trend graphs of the gravimetric energy density of the rate 0.2 C under different mass loads are obtained (Figure S8). The CSe@HNCNFs present high gravimetric energy density of 442.76, 402.58, 383.23 and 353.32 Wh kg\(^{-1}\) at mass loading of 1.52, 7.18, 14.37 and 27.12 mg cm\(^{-2}\), respectively. Fast ion and electron due to N-doping hierarchically porous structure result in high utilization of materials and excellent rate capability of CSe@HNCNFs electrode. As a result, the electrode with various mass loadings displayed continuous higher areal capacities than that of previous Se based cathodes at various current densities (Luo et al., 2013; Li et al., 2014; He et al., 2016; Ding et al., 2018; Xin et al., 2016; Cai et al., 2017; Han et al., 2015; Mukkabla et al., 2017; Wang et al., 2018; Park et al., 2018).

Increasing areal capacity is critical to achieve higher energy and power density, and reducing costs (Gallagher et al., 2016). Therefore, areal capacity is an important index to evaluate the performance of energy storage devices. The specific capacity (mAh g\(^{-1}\)) is given by the relationship between the areal capacity (mAh cm\(^{-2}\)) and the mass loading per unit area (mg cm\(^{-2}\)). As shown in Figure 4d and e, the C-rate and mass loading determine the specific capacity and the areal capacity. As displayed in Figure 5a, the areal capacity increases linearly until 14.37 mg cm\(^{-2}\) at C-rates of 1 and 2 C. At a higher mass loading level, deviation from linearity occurs when the areal capacity starts to reach a platform at 1 C and experiences a decrease in the areal capacity at 2 C. In the linear region, the difference of these slopes is relatively small, because the specific capacity varies very little at different mass loading levels. The platform behavior at 1 C, a sign of the penetration depth of ion current, could be explained by reaching a limit state (Gallagher et al., 2016). Figure 5b shows relationship between areal current density and areal capacity of CSe@HNCNFs electrode with different mass loading levels. An areal capacity of 6.20 mAh cm\(^{-2}\) is
achieved at the high mass loading of 27.12 mg cm$^{-2}$. Each mass loading curve shows the shape of an arc curve: when the current density is low enough and the electrode material is easy to electrolyte infiltration, the areal capacity tends to the maximum value. When the current density increases to more than 3.10 mA cm$^{-2}$, the electrodes under different mass loadings show a significant decline in areal capacity. This phenomenon indicates that ion transport in electrolyte has become a limiting factor under the high current density, which leads to the decrease in areal capacity, and inadequate utilization of the capacity of active electrode (Gallagher et al., 2016). In addition, Figure 5c is the comparison of areal performance metrics between CSe@HNCNFs electrode and other reported cathodes (Luo et al., 2013; Li et al., 2014; He et al., 2016; Ding et al., 2018; Xin et al., 2016; Cai et al., 2017; Han et al., 2015; Mukkabella et al., 2017; Wang et al., 2018; Park et al., 2018). It can be easy to find that when the current density less than 6.10 mA cm$^{-2}$, the CSe@HNCNFs electrode delivers the highest areal capacity among all the Se-based cathodes, implying a tremendous application prospect in the field of energy-storage devices.

**DISCUSSION**

In summary, we proposed a unique covalent selenium embedded in hierarchically porous N-doped carbon nanofibers for advanced Li-Se batteries. When mass loading was 1.87 mg cm$^{-2}$, the Li-Se batteries demonstrated a specific capacity of 762 mAh g$^{-1}$ after 2500 cycles at a constant current rate of 1 C, with almost no attenuation in capacity. We also studied the optimization of charge transfer and high rate energy storage at the ultra-high mass loading level of about 37.31 mg cm$^{-2}$ in a three-dimensional conductive bracket to obtain a particularly high areal capacity of 7.30 mAh cm$^{-2}$ (the highest areal capacity among all the Li-Se batteries). The super-industrial mass loading and areal capacity were obtained, which can also serve as a bridge between the selenium-based cathode and Li-Se batteries for practical application.
Limitations of the Study

Although this covalently structured selenium cathode-based Li-Se batteries display long cycle, high areal capacity, and excellent rate performance, the selenium content of this selenium-based material is relatively low compared to other selenium-based materials. Therefore, future work urgently needs to find a better method that can take into account both the advantages of covalent bonds and the content of selenium.

METHODS

All methods can be found in the accompanying Transparent Methods supplemental file.

Main Figure titles and legends

Figure 1. Morphological characterizations of the HNCNFs and CSe@HNCNFs composites.

(a) Digital photograph of flexible and free-standing CSe@HNCNFs electrode.

(b and c) SEM images of CSe@HNCNFs composite.

(d and e) TEM images of CSe@HNCNFs composite.

(f) HRTEM images of CSe@HNCNFs composite and corresponding FFT pattern.

(g) TEM image and elemental mappings (carbon (h), oxygen (i), nitrogen (j), selenium (k)) of CSe@HNCNFs composite.

Figure 2. Composed characterization of HNCNFs and CSe@HNCNFs composites.

(a) XRD patterns and (b) Raman spectra of the pristine Se powder, HNCNFs, and CSe@HNCNFs.

(c) XPS survey spectra of CSe@HNCNFs.

(d) High-resolution XPS spectra of C 1s for CSe@HNCNFs.

(e) High-resolution XPS spectra of Se 3d for pure Se and CSe@HNCNFs.

(f) High-resolution XPS spectra of N 1s for CSe@HNCNFs.

(g) TG profiles of the obtained composite of CSe@HNCNFs versus HNCNFs.

(h) N₂ adsorption-desorption isothermal curves and (i) corresponding pore-size distribution curves of HNCNFs and CSe@HNCNFs.
Figure 3. Electrochemical properties of Li-Se cells with a CSe@HNCNFs electrodes.

(a) Cyclic voltammograms for the first five cycles obtained at 0.1 mV s\(^{-1}\).

(b) Galvanostatic charge-discharge curves of the CSe@HNCNFs electrode at the rate of 1 C with the mass loading of 1.87 mg cm\(^{-2}\).

(c) Cycling performances and Coulombic efficiencies of the CSe@HNCNFs electrode at rates of 1 and 10 C.

(d) Cycling performances of CSe@HNCNFs electrode at the rate of 1 C under different mass loadings of 1.87, 3.99, 5.27, 7.00 and 14.04 mg cm\(^{-2}\).

Figure 4. Rate capability study of CSe@HNCNFs cathodes.

(a) Galvanostatic charge-discharge curves for the CSe@HNCNFs electrode at a rate of 1 C under the mass loadings of 1.52, 3.63, 5.46, 7.18, 10.64 and 14.37 mg cm\(^{-2}\).

(b and c) Galvanostatic charge-discharge curves at different rates.

(d) Comparison of the rate performance of CSe@HNCNFs electrode at the current rate from 0.2 to 50 C under different mass loadings (1.52, 3.63, 5.46, 7.18, 10.64 and 14.37 mg cm\(^{-2}\)).

(e) Rate performance of CSe@HNCNFs electrode from 0.1 to 2 C when the mass loading is 27.12 mg cm\(^{-2}\).

Figure 5. Performance metrics for electrodes with high mass loading.

(a) The correlation of areal capacity with mass loading (1.52 to 27.12 mg cm\(^{-2}\)) at various C-rates for the CSe@HNCNFs electrode.
(b) The areal performance of the CSe@HNCNFs electrode under different mass loadings.

(c) The comparison of areal performance metrics between CSe@HNCNFs electrode and other Se-based reported cathodes.
- The CSe@HNCNFs was used as flexible and free-standing cathode for Li-Se battery
- The CSe@HNCNFs effectively retards polyselenides diffusion during cycling
- The CSe@HNCNFs delivered high areal capacity of 7.30 mAh cm\(^2\)
- The CSe@HNCNFs displayed excellent cyclic stability and rate performance
