Abstract

We present a detailed investigation of millimeter-wave line emitters ALMA J010748.3-173028 (ALMA-J0107a) and ALMA J010747.0-173010 (ALMA-J0107b), which were serendipitously uncovered in the background of the nearby galaxy VV 114 with spectral scan observations at $\lambda = 2–3$ mm. Via Atacama Large Millimeter/ submillimeter Array (ALMA) detection of CO(4–3), CO(3–2), and [C I](1–0) lines for both sources, their spectroscopic redshifts are unambiguously determined to be $z = 2.4666 \pm 0.0002$ and $z = 2.3100 \pm 0.0002$, respectively. We obtain the apparent molecular gas masses $M_{\text{gas}}$ of these two line emitters from [C I] line fluxes as $(1.12 \pm 0.31) \times 10^{10} M_\odot$ and $(4.2 \pm 1.2) \times 10^{10} M_\odot$, respectively. The observed CO(4–3) velocity field of ALMA-J0107a exhibits a clear velocity gradient across the CO disk, and we find that ALMA-J0107a is characterized by an inclined rotating disk with a significant turbulence, that is, a deprojected maximum rotation velocity to velocity dispersion ratio $v_{\text{max}}/\sigma_{\text{v}}$ of $1.3 \pm 0.3$. We find that the dynamical mass of ALMA-J0107a within the CO-emitting disk computed from the derived kinetic parameters, $(1.1 \pm 0.2) \times 10^{10} M_\odot$, is an order of magnitude smaller than the molecular gas mass derived from dust continuum emission, $(3.2 \pm 1.6) \times 10^{10} M_\odot$. We suggest this source is magnified by a gravitational lens with a magnification of $\mu \gtrsim 10$, which is consistent with the measured offset from the empirical correlation between CO-line luminosity and width.

1. Introduction

In our universe, galaxies form stars most actively at $z = 1–3$ (Hopkins & Beacom 2006; Madau & Dickinson 2014), and their molecular gas content is a key parameter because stars are formed in molecular gas. Therefore, extensive observations of rotational CO lines, which have been established as a useful measure of cold molecular gas mass $M_{\text{gas}}$ (e.g., Bolatto et al. 2013), have been made for various samples of galaxies that are preselected based on their physical properties, such as stellar mass (M$_*$) and star formation rate (SFR), (e.g., Tacconi et al. 2020). This approach has successfully revealed the evolution of molecular gas components by measuring the molecular gas fraction $f_{\text{gas}} = M_{\text{gas}}/(M_{\text{gas}} + M_*)$ in galaxies across cosmic time (e.g., Tacconi et al. 2018, and references therein). Despite the success of this approach, it is also necessary to conduct a blind search of CO-line-emitting galaxies without any priors. This can be accomplished by unbiased spectral scan observations of a region of the sky, which often target known deep fields such as the Hubble Ultra Deep Field (HUDF), where rich multi-wavelength data sets are available. This “deep-field scanning approach” is capable of uncovering galaxies that were not present in standard optical/near-infrared deep surveys, and thus is considered less biased than the pointed approach (Carilli & Walter 2013; Tacconi et al. 2020). Following the pioneering spectral scan observations of the Hubble Deep Field North (HDF-N) using the IRAM Plateau de Bure Interferometer (Decarli et al. 2014), the Atacama Large Millimeter/submillimeter Array (ALMA) has been exploited to conduct spectral scan observations of the HUDF (e.g., Walter et al. 2016; Aravena et al. 2019), SSA22 (Hayatsu et al. 2017, 2019), and lensing clusters (e.g., González-López et al. 2017; Yamaguchi et al. 2017) to uncover millimeter-wave line-emitting galaxies and constrain both CO line luminosity functions and the cosmic molecular gas mass density evolution (e.g., Decarli et al. 2020) as a function of redshift.

In addition to these dedicated spectral scan observations of deep fields, there are mounting examples of serendipitous discovery of millimeter-wave line emitters. They were detected using ALMA and the Northern Extended Millimeter Array and in the data from the second Plateau de Bure High-$z$ Blue Sequence Survey, within a field of view (FoV) of, for example, a nearby galaxy (e.g., Tamura et al. 2014) and high-$z$ source (e.g., Swinbank et al. 2012; Gowardhan et al. 2017; Wardlow et al. 2018; Lenkic et al. 2020). Currently, the nature of such serendipitously uncovered millimeter-wave line emitters remains unexplored, given the very limited number of such sources, but it is important to characterize the known line
emitters because we can learn which types of galaxies can be selected from monotonically increasing numbers of spectral cubes in the ALMA science archive over time.

Here, we report a detailed investigation of millimeter-wave line emitters ALMA J010748.3-173028 (ALMA-J0107a) and ALMA J010747.0-173010 (ALMA-J0107b), which were serendipitously uncovered around the nearby galaxy VV 114 with spectral scan observations at $\lambda = 2$–3 mm. We display the positions of ALMA-J0107a and ALMA-J0107b in Figure 1 (top), in which an HST I-band image of VV 114 is shown. As VV 114 is one of the best-studied archetypical luminous infrared galaxies (LIRGs) in the local universe (e.g., Iono et al. 2013; Saito et al. 2015, 2017), a number of spectral scan observations have been conducted using ALMA. The discovery of ALMA-J0107a was first reported by Tamura et al. (2014), based on a single line detection in ALMA band 3. Although the multiwavelength counterpart identification at the position of ALMA-J0107a favors a CO(3–2) line at $z = 2.467$, the proximity of ALMA-J0107a to the local LIRG VV 114 ($\sim 10''$ from the eastern nucleus of VV 114) hampers reliable photometric constraints at near-to-far-infrared bands and therefore requires other transitions of CO to obtain an unambiguous spectroscopic redshift. Tamura et al. (2014) also found the hard X-ray source at the position of ALMA-J0107a in Chandra/ACIS-I data (see Figure 1 (a)), which suggested the presence of an active galactic nucleus (AGN). ALMA-J0107b is also serendipitously detected in the line scan of the VV 114 field at $\alpha = 0^\mathrm{h}0^\mathrm{m}46.99^\mathrm{s}, \delta = -17^\circ30'00''$, and we report it in this paper. Figure 1(a) and (b) shows multiwavelength images of both ALMA-J0107a and ALMA-J0107b. It contains three Spitzer/IRAC band images, as well as the Chandra/ACIS-I image.

The remainder of this paper is organized as follows: The reduced ALMA data and reduction procedures are described in Section 2, along with the derived line spectra. The physical quantities derived from the observed lines and continuum emissions are summarized in Section 3. Section 4 is devoted to kinematic modeling of the observed CO velocity field of ALMA-J0107a. After discussing the nature of the millimeter-wave line emitters in Section 5, we summarize our findings in Section 6. We assume a $\Lambda$CDM cosmology with $\Omega_m = 0.3$, $\Omega_{\Lambda} = 0.7$, and $H_0 = 68$ km s$^{-1}$ Mpc$^{-1}$.

2. Data Analysis

2.1. Selection, Reduction, and Imaging

We analyzed the ALMA data listed in Table 1, which targeted VV 114 and include J0107a and J0107b within the
Table 1

Notes.

<sup>a</sup> Target a represents J0107a, and target b represents J0107b.

<sup>b</sup> Suggested emission lines are detected only with the target suggested in this table.

The zoom-in spectrum of each detected line with the best-fit Gaussian profiles is shown in Figure 3. Each spectrum in this figure was made by taking an aperture of ~3″ × 3″ square centered at the peak position. The line width of each line is measured as the full width at half maximum (FWHM) of these Gaussian profiles.

We made channel maps for each line in order to measure line properties and to create moment maps. We set the velocity resolution of the channel map that includes CO(4–3) of J0107a to be 20 km s<sup>−1</sup>, and used a velocity resolution of 50 km s<sup>−1</sup> for the other maps. The derived physical properties, achieved peak S/N in channel maps, and typical noise level for each line are listed in Table 2.

To create all moment maps (zeroth, first, and second), we included approximately ±150 km s<sup>−1</sup> around the line center. In addition, to create the first and second moment maps, we set a masking threshold with a range of 2σ–4σ of these line data. We arbitrarily set these clipping thresholds for each data cube in order to make these maps clear. We do not adopt this clipping procedure for zeroth-moment maps, hence the total fluxes of all lines are correctly measured. In fact, the total fluxes derived from moment maps are quite consistent with those from integration of the Gaussian fitting for line spectra (Figure 3) for all emission lines. We measure the integrated line fluxes S<sub>obs</sub> and beam deconvolved source sizes of each line using the CASA TASK IMFIT for zeroth-moment maps with the default setting.

Moment maps for the three emission lines are presented in Figures 4 and 5.

2.3. Continuum Measurement

We analyzed the entire collection of data from ALMA bands 3, 4, 6, and 7 using the line-free channels to obtain the dust continuum properties (Table 3). We obtain flux values using the CASA TASK IMFIT by setting the same area as we set to obtain line spectra in Figure 3. The rms noise levels are measured using the CASA TASK IMSTAT with algorithm BWEIGHT over the entire FoV. Here, we did not detect the continuum of J0107a in band 3 nor that of J0107b in bands 3 and 4; hence, we present the 3σ upper limits for flux values in these bands. The intensity maps for the continuum in these bands are presented in Figures 4 and 5. Because both J0107a and J0107b are located close to the edge of the band 7 FoV,
these maps appear noisy. However, the noise levels in the vicinity of the sources are consistent with those measured over the entire field, suggesting no significant effect of the position on the map.

3. Results

3.1. Molecular Gas Mass by Emission Lines

The molecular gas mass can be calculated from both the CO and [C I] line luminosities. The molecular gas mass derived from the CO line luminosity has an uncertainty caused by the excitation and the choice of a CO-to-H$_2$ conversion factor $\alpha_{\text{CO}}$. Although the molecular gas mass derived from [C I](1–0) has a similar uncertainty due to the [C I] abundance, this can be used for reasonable estimation of H$_2$ and molecular gas mass because of its simple partition function and chemistry (Alaghband-Zadeh et al. 2013; Saito et al. 2020). In this section, we first calculate $M_{\text{gas}}$ with the [C I] line luminosity, and compare these results with $M_{\text{gas}}$ derived with CO line luminosity and typical $\alpha_{\text{CO}}$ for high-redshift galaxies. Hereafter, we adopt some parameters and equations for submillimeter galaxies (SMGs) from previous studies, such as CO line luminosity ratio, dust temperature $T_{\text{dust}}$, Equations (3), and (8), because the properties of J0107a and J0107b based on the analysis in this study, such as submillimeter fluxes and star formation rate, are SMG-like (see Table 3 and Section 3.3 regarding J0107a).
The three spectral lines, CO(4–3), CO(3–2), [C I](1–0), in each of J0107a (a) and J0107b (b). The black solid curve drawn in each plot is the result of Gaussian fitting to each line. The velocity resolution of the data is 20 km s\(^{-1}\) for CO(4–3) of J0107a and 50 km s\(^{-1}\) for the others.

Table 2
Summary of the Analysis of Detected Emission Lines in This Study

|          | J0107a CO(4–3) | J0107b CO(4–3) | J0107a [C I](1–0) | J0107b [C I](1–0) |
|----------|----------------|----------------|------------------|------------------|
| \(\nu_{\text{obs}}\) (GHz) | 132.99 | 99.749 | 141.97 | 139.29 | 104.47 | 148.69 |
| Line peak (mJy beam\(^{-1}\)) | 2.29 ± 0.11 | 1.88 ± 0.12 | 0.93 ± 0.13 | 1.77 ± 0.10 | 1.06 ± 0.12 | 0.38 ± 0.05 |
| rms (mJy beam\(^{-1}\)) | 0.54 | 0.42 | 0.46 | 0.33 | 0.37 | 0.32 |
| Beam size | \(1.53 \times 1.52\) | \(1.54 \times 1.53\) | \(1.57 \times 1.50\) | \(1.52 \times 1.55\) | \(1.56 \times 1.51\) | \(1.50 \times 1.52\) |
| Deconvolved source size | \(1.53 \times 0.57\) | \(1.54 \times 0.57\) | \(1.57 \times 0.53\) | \(1.52 \times 0.55\) | \(1.56 \times 0.51\) | \(1.50 \times 0.53\) |
| \(S_{\text{obs}}\) (Jy km s\(^{-1}\)) | 3.0 ± 0.2 | 2.2 ± 0.2 | 1.2 ± 0.2 | 1.3 ± 0.1 | 0.95 ± 0.1 | 0.51 ± 0.1 |
| Luminosity (10\(^{10}\) K km s\(^{-1}\) pc\(^{2}\)) | 5.7 ± 0.4 | 7.2 ± 0.5 | 2.0 ± 0.3 | 2.1 ± 0.2 | 2.8 ± 0.3 | 0.75 ± 0.1 |
| Line FWHM (km s\(^{-1}\)) | 193 ± 11 | 165 ± 13 | 217 ± 34 | 190 ± 13 | 164 ± 21 | 176 ± 27 |
| Peak S/N in channel maps | \(~20\) | \(~15\) | \(~10\) | \(~11\) | \(~9\) | \(~3\) |

Note. The line peaks are those of line spectra in Figure 3. The source size and velocity-integrated flux density \((S_{\text{obs}})\) are measured with the CASA TASK IMFIT, and we applied primary beam correction for \(S_{\text{obs}}\). The velocity resolution is 20 km s\(^{-1}\) for the data of CO(4–3) of J0107a and 50 km s\(^{-1}\) for other data. Source sizes have 5%–10% errors for each axis. The peak S/N is the approximate ratio of line peak in Figure 2 and rms noise for each line.

We calculate the \(\text{H}_2\) mass using the formula given by Alaghband-Zadeh et al. (2013) (and references therein):

\[
M_{\text{H}_2} = 1375.8 \times \frac{D_L^2}{1 + z} \left( \frac{X_{\text{C}_1}}{1.5 \times 10^{-5}} \right) \left( \frac{A_{10}}{1.0 \times 10^{-15} \text{ s}^{-1}} \right)^{-1} \times Q_{10} \times \frac{S_{\text{C}_1}}{\text{Jy km s}^{-1}} [M_\odot].
\] (1)

where \(D_L\) is the luminosity distance in Mpc (20656 Mpc for J0107a and 19073 Mpc for J0107b), \(X_{\text{C}_1}\) is the flux density of the [C I](1–0) line, \(A_{10} = 7.93 \times 10^{-8} \text{ s}^{-1}\) is the Einstein A coefficient, \(X_{\text{C}_1} = [\text{C I}] / [\text{H}_2] = (5.0 - 7.9) \times 10^{-5}\) is the [C I] abundance relative to \(\text{H}_2\) for SMGs at \(z > 2.5\) (Valentino et al. 2018, and references therein), and \(Q_{10} = Q_{10}(n, T_{\text{ex}}) = 0.49 \pm 0.02\) (Alaghband-Zadeh et al. 2013) is the partition function, which depends on the gas excitation conditions (Papadopoulos & Greve 2004), and here the excitation temperature is assumed to be about 30 K (Alaghband-Zadeh et al. 2013). While \(A_{10}\) is naturally a physical constant, \(X_{\text{C}_1}\) and \(Q_{10}\) are empirical parameters.

By multiplying the \(\text{H}_2\) mass, calculated from Equation (1), by 1.36 to account for the He contribution, we derive the total molecular gas mass \(M_{\text{gas}}\):

\[
M_{\text{gas}}(\text{J0107a}) = (11.2 \pm 3.1) \times 10^{10} M_\odot,
\]

\[
M_{\text{gas}}(\text{J0107b}) = (4.2 \pm 1.2) \times 10^{10} M_\odot.
\]

The dominant factor in the error is the uncertainty in \(X_{\text{C}_1}\).

On the other hand, \(M_{\text{gas}}\) can be derived from the CO(1–0) luminosity and \(\alpha_{\text{CO}}\) as:

\[
\frac{M_{\text{gas}}}{M_\odot} = \alpha_{\text{CO}} \left( \frac{L'(\text{CO}_{1-0})}{\text{K km s}^{-1} \text{pc}^2} \right).
\] (2)

We here estimate \(M_{\text{gas}}\) by assuming \(\alpha_{\text{CO}} = 0.8\) (Downes & Solomon 1998), which is commonly adopted for high-redshift galaxies, and converting CO(4–3) and CO(3–2) luminosities to that of CO(1–0) based on SMGs’ line ratios \(L'(\text{CO}_{4-3}) / L'(\text{CO}_{1-0}) = 0.32 \pm 0.05\), and \(L'(\text{CO}_{3-2}) / L'(\text{CO}_{1-0}) = 0.60 \pm 0.11\) (Birkin et al. 2021). The results are \(M_{\text{gas}}(\text{J0107a}) = (13.4 \pm 1.7) \times 10^{10} M_\odot\) and \(M_{\text{gas}}(\text{J0107b}) = (5.0 \pm 0.7) \times 10^{10} M_\odot\) for CO(4–3) luminosities, and \(M_{\text{gas}}(\text{J0107a}) = (9.2 \pm 1.9) \times 10^{10} M_\odot\) and \(M_{\text{gas}}(\text{J0107b}) = (3.6 \pm 0.8) \times 10^{10} M_\odot\) for CO(3–2) luminosities. These results are consistent with the \(M_{\text{gas}}\) based on [C I] within uncertainties.

3.2. Molecular Gas Mass by Dust Continuum

For local galaxies, ULIRGs, and redshifted SMGs observed at wavelengths longer than 250 \(\mu\text{m}\), in which we may assume that the emission is in the Rayleigh–Jeans tail, Scoville et al. (2016) presented that \(M_{\text{gas}}\) can be derived from the dust
continuum emission as follows:

\[
\frac{M_{\text{gas}}}{10^{10} M_\odot} = 1.78(1+z)^{-4.8} \times \left( \frac{S_{\text{obs}}}{\text{mJy}} \right)^{3.8} \left( \frac{\nu_{\text{obs}}}{353 \text{ GHz}} \right)^{-3.8} \times \left( \frac{6.7 \times 10^{19}}{\alpha_{353 \text{ GHz}}} \right) \frac{D_L}{\Gamma_{\text{RJ}} (\text{Gpc})^2},
\]

where

\[
\frac{\alpha_{353 \text{ GHz}}}{\text{erg s}^{-1} \text{Hz}^{-1} M_\odot^{-1}} = L_{353 \text{ GHz}} / M_{\text{gas}},
\]

\[
\Gamma_{\text{RJ}}(T_{\text{dust}}, \nu_{\text{obs}}, z) = \frac{\hbar \nu_{\text{obs}}(1+z)}{kT_{\text{dust}}} \frac{1}{e^{\hbar \nu_{\text{obs}}(1+z)/kT_{\text{dust}} - 1}},
\]

and \( \Gamma_0 = \Gamma_{\text{RJ}}(T_{\text{dust}}, 353 \text{ GHz}, 0) \).

Figure 4. CO, [C I], and continuum images of J0107a. Each panel depicts a 10\arcsec\times10\arcsec region centered on the CO(4–3) peak position. Panels (a1), (a2), and (a3): Velocity-integrated intensity images of CO(4–3), CO(3–2), and [C I](1–0) lines. Contour levels are 10σ, 20σ, and 30σ, where 1σ = 0.018, 0.031, and 0.031 Jy beam\(^{-1}\) km s\(^{-1}\) for CO(4–3), CO(3–2), and [C I](1–0) lines, respectively. Panels (a4), (a5), and (a6): Intensity-weighted mean radial velocity images of CO(4–3), CO(3–2), and [C I](1–0) lines. Contour levels are −60, −40, −20, 0, 20, and 40 km s\(^{-1}\) for CO(4–3), −40, −20, 0, 20, and 40 km s\(^{-1}\) for CO(3–2), and −20, 0, 20, and 40 km s\(^{-1}\) for [C I](1–0). Negative contours are dashed. Panels (a7), (a8), and (a9): Intensity-weighted velocity dispersion images of CO(4–3), CO(3–2), and [C I](1–0) lines. Contour levels are 20, 40, and 60 km s\(^{-1}\) for CO(4–3) and CO(3–2), and 20 and 40 km s\(^{-1}\) for [C I](1–0). Panels (a10), (a11), (a12), and (a13): Continuum images of 3.0 mm (band 3), 2.2 mm (band 4), 1.3 mm (band 6), and 0.89 mm (band 7). Contour levels are 1σ (band 3), 2σ and 3σ (band 4), and 2σ, 3σ, and 5σ (bands 6 and 7). Each noise level is given in Table 3 (rms in mJy beam\(^{-1}\)). The band 7 continuum image (a13) has relatively large noise in the left side because J0107a is near the east edge of the field.
We use our ALMA/band 6 data for calculation of $M_{\text{gas}}$ of J0107a. Because our current data set cannot constrain $T_{\text{dust}}$, we assume $T_{\text{dust}} = 40$ K, which is given by the surveys of SMGs and galaxies in $0 < z < 4$ (da Cunha et al. 2015; Schreiber et al. 2018). Here, we should note that this $T_{\text{dust}}$ is luminosity-weighted and is likely higher than a mass-weighted $T_{\text{dust}}$, such as that suggested in Scoville et al. (2014). Consequently, the $M_{\text{gas}}$ of J0107a is calculated as below:

$$M_{\text{gas}}(\text{J0107a}) = (3.2 \pm 1.6) \times 10^{11} M_\odot.$$  

Here, we adopt $\alpha_{353\text{GHz}} = 8.4 \times 10^{19}$ erg s$^{-1}$ Hz$^{-1}$ M$^{-1}_\odot$, which is derived as the mean value for $z \sim 2$ SMGs in Scoville et al. (2016). We also set a typical uncertainty of the derived $M_{\text{gas}}$ as $\pm 50\%$ (Scoville et al. 2014). If $T_{\text{dust}} = 30$ K and 50 K are adopted, $M_{\text{gas}}$ becomes $M_{\text{gas}}(\text{J0107a}) = (3.6 \pm 1.8) \times 10^{11} M_\odot$, and $M_{\text{gas}}(\text{J0107a}) = (3.0 \pm 1.5) \times 10^{11} M_\odot$, respectively. Hence, the result may change from approximately 6%-12% with a $T_{\text{dust}}$ error of 10 K. We calculate the $M_{\text{gas}}$ of J0107b in the same manner as follows:

$$M_{\text{gas}}(\text{J0107b}) = (9.5 \pm 4.8) \times 10^{10} M_\odot.$$  

The result of J0107b also changes approximately 6%-12% with a $T_{\text{dust}}$ error of 10 K.

The similarity between the cold gas mass derived from the lines and from the dust continuum supports the derived cold gas mass.
3.3. Far-IR Luminosity and SFR

In star-forming galaxies (SFGs), most infrared emissions are believed to be emitted from warm dust around young stars, and thus, their SFR is calculated from the infrared luminosity $L_{\text{FIR}}$ (Kennicutt 1998; Carilli & Walter 2013). Although we can also assume AGN to be a heat source, Brown et al. (2019) reported that the AGN contribution to $L_{\text{FIR}}$ is typically smaller than 10% when $L_{\text{FIR}} \sim 10^{13} L_{\odot}$. Here, we estimate the SFR of J0107a and J0107b using the far-infrared luminosity $L_{\text{FIR}}$ because of the lack of LIR data. By assuming the graybody model $F_{\nu} \propto \nu^{\beta}B(\nu, T)$, we derive $L_{\text{FIR}}$ with the formula in De Breuck et al. (2003):

$$L_{\text{FIR}} = 4\pi\Gamma[\beta + 4] \zeta[\beta + 4] D_L^2 \left(\frac{h\nu_{\text{rest}}}{kT_{\text{dust}}} - 1\right) S_{\text{obs}} \nu_{\text{obs}} T_{\text{dust}}$$

where $\beta$ is the index, $\Gamma[x]$ is the gamma function, and $\zeta[x]$ is the zeta function. Assuming $\beta = 1.5$ and $T_{\text{dust}} = 40$ K, we calculate $L_{\text{FIR}}$ of J0107a and J0107b using this formula as

$$L_{\text{FIR}}(\text{J0107a}) = (10.3 \pm 0.8) \times 10^{12} L_{\odot}$$
$$L_{\text{FIR}}(\text{J0107b}) = (3.0 \pm 0.6) \times 10^{12} L_{\odot}.$$  

Here, we used band 6 data, in which both targets are clearly identified. For a sanity check, we also calculate $L_{\text{FIR}}$ with other continuum data. For J0107a, we derived $L_{\text{FIR}} < 12.3 \times 10^{12} L_{\odot}$, $L_{\text{FIR}} = (10.2 \pm 2.0) \times 10^{12} L_{\odot}$, and $L_{\text{FIR}} = (9.0 \pm 1.1) \times 10^{12} L_{\odot}$, with band 3, 4, and 7 data, respectively. These results are all consistent with each other. We calculate for J0107b with the same manner as $L_{\text{FIR}} < 12.3 \times 10^{12} L_{\odot}$, $L_{\text{FIR}} < 7.2 \times 10^{12} L_{\odot}$, and $L_{\text{FIR}} = (5.8 \pm 1.4) \times 10^{12} L_{\odot}$, with band 3, 4, and 7 data, respectively. They are also comparable to each other. The $L_{\text{FIR}}$ of J0107b derived from band 7 data is a little larger than that from band 6 data. This may be because of poorer fitting in band 7 data due to apparent multiple peaks.

Regarding $L_{\text{FIR}}$, the results change by a factor of 2 when $T_{\text{dust}}$ changes by 10 K. The results also depend on $\beta$. Chapin et al. (2009) derived $\beta = 1.75$ for 29 SMGs with a median redshift $z = 2.7$ with a 1.1 mm survey. The Planck Collaboration et al. (2011) similarly suggested $\beta = 1.8 \pm 0.1$ based on the all-sky observation results, and Scoville et al. (2014) adopted $\beta = 1.8$ after this result. If we adopt $\beta = 1.8$ for our calculation of $L_{\text{FIR}}$, the results with $T_{\text{dust}} = 40$ K increase by about a factor of 1.5 ($L_{\text{FIR}}(\text{J0107a}) = 1.7 \times 10^{13} L_{\odot}$ and $L_{\text{FIR}}(\text{J0107b}) = 5.0 \times 10^{12} L_{\odot}$, respectively). Consequently, the total systematic uncertainty of $L_{\text{FIR}}$, due to the selection of $T_{\text{dust}}$ and $\beta$, is about a factor of 3.

The relationship between SFR and $L_{\text{FIR}}$ is shown in Genzel et al. (2010) as follows:

$$\log_{10}\left(\frac{\text{SFR}}{M_{\odot} \text{yr}^{-1}}\right) = \log_{10}\left(\frac{L_{\text{FIR}}}{L_{\odot}}\right) + \log_{10}(1.3) - 10,$$  

where $\log(1.3)$ is a correction factor between $L_{\text{IR}}$ and $L_{\text{FIR}}$ (Graciá-Carpio et al. 2008), and the typical uncertainty of this equation is about ±50% (Genzel et al. 2010). The derived SFRs are $1.3 \times 10^{5} M_{\odot} \text{yr}^{-1}$ and $3.9 \times 10^{2} M_{\odot} \text{yr}^{-1}$ for J0107a and J0107b, respectively, and the typical systematic uncertainties of these SFRs are about a factor of 4.5, which is mainly attributed to the uncertainties of $L_{\text{FIR}}$ and the Equation (7). The physical quantities derived from our data analysis are summarized in Table 4 and discussed in Section 5.

4. Kinematic Modeling

In this section, we perform kinematic modeling of a rotating disk to derive a rotation curve and estimate some dynamical properties. Here, we discuss only J0107a. Although the CO(4–3) line of J0107b indicates the rotational motion (see Figure 5), the S/N is not enough for the kinematic modeling.

4.1. Method and Results

We model the disk rotation of J0107a using the Markov chain Monte Carlo (MCMC) method with GalPaK3D (Bouché et al. 2015). We use the CO(4–3) data cube (2D image and frequency dimension) for the modeling, which has a better S/N.
than those of CO(3–2) or [C I](1–0). The algorithm directly compares the data cube with a disk parametric model with ten free parameters: coordinates of the galaxy center (x, y, z), flux, half-light radius, inclination angle (i), position angle (PA), turnover radius of the rotation curve, deprojected maximum rotation velocity, and intrinsic velocity dispersion. We first perform modeling with ten free parameters, and then repeat it by setting the initial values for x, y, z, and i. We assume a rotational velocity with a hyperbolic tanh profile in this model. The uncertainty is the 95% confidence interval (CI) calculated from the last 60% of the MCMC chain for 20,000 iterations. We here set the random scale of MCMC chain as 0.4 to obtain its acceptance rate of 30%–40% in this modeling. Furthermore, by setting a beam size, the effect of beam smearing is considered in the modeling.

The initial value for i is set to be 60°, based on the ratio of the major axis to the minor axis of the beam-deconvolved source size of the 1.3 mm continuum. We confirm that setting initial values to be 20° or 40° does not greatly change the results, and hereafter we present results with i = 60° only. We then obtain a GalPaK3D model, and the inclination angle converges to approximately 63°. This result indicates that J0107a is unlikely to be face-on, and the major/minor ratio of the model (=2.2 ± 0.1) is consistent with the observed source sizes of 1.3 mm, 0.89 mm, and CO(4–3) emission. In addition, the half-light radius of the model is consistent with the deconvolved half width at half maximum of J0107a (=5.4 ± 0.5 kpc), which is derived by the CASA TASK IMFIT for the CO(4–3) source in the band 4 data. We also obtain the maximum rotation velocity as v_{max} = 69.3 ± 4.8 km s⁻¹, and the velocity dispersion as σ_v = 54.6 ± 1.8 km s⁻¹. In GalPaK3D, velocity dispersion is estimated by assuming three components, one of which is an intrinsic velocity dispersion (Bouché et al. 2015), and the σ_v of J0107a here is the result for the intrinsic velocity dispersion. Therefore, we hereafter treat the σ_v of J0107a as an intrinsic value. We summarize the results of the GalPaK3D model in Table 5. Figure 6 shows the output rotation curve, and Figure 7 shows a comparison of the GalPaK3D model with the observational data of J0107a on CO(4–3) intensity and velocity maps. Figure 8 shows the position–velocity diagram of J0107a and the contours of its model by GalPaK3D. Both of the velocities in this diagram are extracted along the lines shown in the black dotted lines in panels (d) and (e) of Figure 7, the PA of which is 110° 4. As we can see in Figure 8, the velocity of J0107a changes continuously from v ~ -120 km s⁻¹ to ~ +120 km s⁻¹, and there are apparently two peaks at v ~ -20 km s⁻¹ and v ~ +40 km s⁻¹ in this diagram. This result suggests that J0107a is less likely to be a galaxy merger. All of these results suggest that J0107a has a rotating disk. Additionally, we show the plot of cross-correlations in the Markov chain in the Appendix.

### Table 5

| J0107a | Value | 95% CI |
|--------|-------|-------|
| Flux [Jy beam⁻¹] | 1.83 ± 0.02 | [1.78, 1.88] |
| Half-light radius [kpc] | 4.91 ± 0.1 | [4.71, 5.13] |
| Inclination [deg] | 63.2 ± 1.7 | [59.8, 66.8] |
| PA [deg] | 290.4 ± 1.5 | [287.5, 293.2] |
| Turnover radius [kpc] | 0.697 ± 0.772 | [0.05, 2.711] |
| Maximum velocity [km s⁻¹] | 69.31 ± 4.79 | [64.45, 82.53] |
| Velocity dispersion [km s⁻¹] | 54.57 ± 1.78 | [51.48, 58.35] |

### 4.2. Dynamical Mass

In the calculation of a dynamical mass, M_{dyn}, we use the results of GalPaK3D. As for the radius, we regard a value equal to twice the half-light radius, which corresponds to \( r = 9.8 ± 0.2 \) kpc (1.2° ± 0.07°), as the radius of J0107a. We use this r and the best-fit value of v_{max} from the model to estimate M_{dyn}, and derive it as follows:

\[
M_{\text{dyn}}(\text{J0107a}) = \frac{r_{\text{max}}^2}{G} = (1.1 ± 0.2) \times 10^{10} \, M_\odot.
\]

Here, G is the gravitational constant, and \( 1.1 \times 10^{10} \, M_\odot \) is the 50th percentile of the results of M_{dyn} for each 12,000 iterations after MCMC burn-in. This is an order of magnitude smaller than M_{gas(dust)} derived in Section 3.2. The possible origins of this discrepancy are discussed in the next section.

### 5. Discussion

Here, we mainly discuss the physical properties of J0107a. Specifically, we focus on the ratio of maximum rotation velocity v_{max} to velocity dispersion \( \sigma_v \), v_{max}/\sigma_v, to assess the dynamic hotness of the gas disk, and the molecular gas fraction f_{gas} = M_{gas}/(M_{gas} + M_\star), where M_\star is the stellar mass of the galaxy, to characterize the evolutionary state of the system. The possible cause of the discrepancy between M_{gas} and M_{dyn}, which is found to be of an order of magnitude, is also discussed in this section.

### 5.1. Dynamical Properties of the Gas Disk

We obtain v_{max}/\sigma_v = 1.3 ± 0.1 using the best-fit kinetic parameters in Section 4. Here, 1.3 is the 50th percentile of the results for each 12,000 iterations after MCMC burn-in, similar to M_{dyn}. The error of v_{max}/\sigma_v is also calculated with the use of each result of 12,000 iterations. As a more conservative estimate on the error in \( \sigma_v \), we adopt the error of the spectral line width derived by the Gaussian fitting (Table 2). The largest
The modeled CO (4–3) integrated intensity map from the best-fit GalPaK results. Panel (a): The observed CO (4–3) integrated intensity map, the contours show 5σ, 10σ, 20σ, and 30σ of the data, and contours with the same levels are also shown in (b). Panel (b): The modeled CO (4–3) integrated intensity map from the best-fit GalPaK results. Panel (c): The residual of the CO (4–3) integrated intensity map, (a)–(b). The contours show ±5σ of the data. Panel (d): The observed CO (4–3) velocity map. The contour interval in panels (d), (e), and (f) is 20 km s\(^{-1}\), and negative contours are dashed. Panel (e): The modeled CO (4–3) velocity map from the GalPaK model. The velocities in the position–velocity diagram in Figure 8 are extracted along the dotted line shown in (d) and (e). Panel (f): The residual CO (4–3) velocity map, (d) and (e).

Figure 9 shows the relation between \(v_{\text{max}}/\sigma\_e\) of SFGs (data from Swinbank et al. 2017; Lee et al. 2019), SMGs (data from Alaghband-Zadeh et al. 2012; Hodge et al. 2012; De Breuck et al. 2014; Tadaki et al. 2019; Jiménez-Andrade et al. 2020), millimeter-wave line emitter samples in Kaasinen et al. (2020), and J0107a.

Burkert et al. (2010) mentioned that \(z \sim 1.5–3.5\) SFGs have large gas velocity dispersions of 30–120 km s\(^{-1}\) and ratios of \(v_{\text{max}}/\sigma\_e\sim 1–6\). This is supported by the observations of \(z \sim 0.3–1.7\) SFGs (Swinbank et al. 2017) and SFGs in a protocluster at \(z \sim 2.5\) (Lee et al. 2019). Alaghband-Zadeh et al. (2012) investigated the H\(\alpha\) velocity fields of SMGs in \(z \sim 2–3\) and derived \(v_{\text{max}}/\sigma \sim 1–3\) (average \(1.9 \pm 0.2\)). Kaasinen et al. (2020) also reported \(v_{\text{max}}/\sigma\_e\sim 5\) for their millimeter-wave line emitter samples in \(z = 1.4–2.7\), and noted that this value was higher than those of typical high-redshift galaxies due to a selection bias. They also noted that the velocity dispersions of their samples were global estimates that include dispersions due to motion along the line of sight (i.e., due to motion inside a thick disk, or motions due to warps), and they treated their velocity dispersions as upper limits. However, this discussion can be applied to the \(\sigma\_e\) of other samples—which were derived with, for example, line width—and does not significantly affect our results. We therefore do not strictly consider it here. Because of this reason, here we do not treat the \(\sigma\_e\) of Kaasinen et al.’s samples as upper limits, as with other samples.

Consequently, from a quantitative point of view, the \(v_{\text{max}}/\sigma\_e\) ratio of J0107a seems smaller than those of other line emitters, and at the same level as those of SMGs at similar redshifts.
Simons et al. (2017) showed that the \( \frac{v_{\text{max}}}{\sigma_v} \) ratio of an SFG is affected by stellar mass; hence, we show the fitting results for the distribution of \( \frac{v_{\text{max}}}{\sigma_v} \) ratios of typical SFGs with low stellar mass (\( M_* \sim 10^9 - 10^{10} \, M_\odot \)) and those with high stellar mass (\( M_* \sim 10^{10} - 10^{11} \, M_\odot \)), respectively, in Figure 9. In this figure, the \( \frac{v_{\text{max}}}{\sigma_v} \) ratios of almost all line emitters and SMGs, which have stellar masses of approximately \( 10^{11} \, M_\odot \), are consistent with the fitting result for high-\( M_* \) SFGs within uncertainties. The SFG samples in this figure have a very wide range of stellar mass (\( M_* \sim 10^9 - 10^{11} \, M_\odot \)), but their \( \frac{v_{\text{max}}}{\sigma_v} \) ratios are also consistent with the fitting lines within uncertainties.

The \( \frac{v_{\text{max}}}{\sigma_v} \) ratio of J0107a is consistent with the fitting for both low and high stellar masses within the errors. The stellar mass of J0107a is derived as \( M_* \leq 1.0 \times 10^{11} \, M_\odot \) (see Section 5.2), but considering the gravitational lensing (see Section 5.3), it may be more appropriate to conclude that the \( \frac{v_{\text{max}}}{\sigma_v} \) ratio of J0107a is consistent with the fitting for low stellar mass, whereas it is difficult to constrain the range of \( M_* \) by the \( \frac{v_{\text{max}}}{\sigma_v} \) ratio alone.

### 5.2. Molecular Gas Fraction

To obtain \( f_{\text{gas}} \), we first calculate \( M_* \). Hainline et al. (2011) used a sample of \( \sim 70 \) SMGs to derive the ratio between \( M_* \) and the rest-frame near-infrared (\( H \)-band) luminosity \( L_H \) for two star formation histories, instantaneous starburst and constant star formation (CSF), by taking the average of best-fit model ages over the sample. Consequently, they obtained the relation between \( M_* \) and \( L_H \) of SMGs for the population synthesis model of Bruzual & Charlot (2003) and CSF history as below within a factor of 2–3:

\[
\frac{M_*}{M_\odot} = \frac{1}{5.8} \left( \frac{L_H}{L_\odot} \right).
\]

Considering \( \lambda_H = 1.65 \, \mu m \), the observed wavelength is 5.72 \( \mu m \) with \( z = z(\text{J0107a}) \). Therefore, we first use the intensity data in the nearest band, IRAC/5.8 \( \mu m \) (Tamura et al. 2014), which is equal to \( S_{\text{obs}} \leq 0.1 \) mJy (upper limit), and obtain the \( L_H \) of J0107a as follows:

\[
L_H \sim 4 \pi D_L^2 \times S_{\text{obs}}, \quad \text{where} \quad \nu = 4.4 \times 10^{13} \text{ Hz is the bandwidth of the IRAC/5.8 \( \mu m \) band, which is calculated by the bandwidth in the wavelength scale } \frac{d\lambda}{d\nu} = 0.41 \mu m \text{ in } z = z(\text{J0107a}).
\]

Consequently, \( M_* \) is calculated as follows:

\[
M_*(\text{J0107a}) < 1.0 \times 10^{11} \, M_\odot.
\]

We can also estimate \( M_* \) with the use of IRAC/4.5 \( \mu m \) and IRAC/3.6 \( \mu m \) data (Tamura et al. 2014) as \( M_* = 7.1 \times 10^{10} \, M_\odot \) and \( 5.5 \times 10^{10} \, M_\odot \), respectively, but we adopt the result from IRAC/5.8 \( \mu m \) in order to avoid possible extinction effect. We note again that the photometry of these data is uncertain due to the foreground emission from VV114, and we should regard the \( M_* \) as an upper limit.

The \( f_{\text{gas}} \) of J0107a is then calculated using the results of previous calculations as

\[
f_{\text{gas}}(\text{J0107a}) > 0.5.
\]

This fraction may contain additional uncertainty caused by differential magnification (Hezaveh et al. 2012; Serjeant 2012).
between stellar emission and gas emission, considering the possibility of strong magnification of J0107a (see Section 5.3).

5.3. Why Does the Molecular Gas Mass Exceed the Dynamical Mass in J0107a?

Considering the dark matter contribution, $M_{\text{dyn}}$ should generally be consistent with, or larger than, $M_{\text{gas}} + M_*$ within uncertainties. However, we find that, for J0107a, $M_{\text{dyn}}$ is an order of magnitude smaller than $M_{\text{gas}}$. This discrepancy cannot be attributed to the $M_{\text{gas}}$ overestimation, because all values of $M_{\text{gas}}$, yielded by the data of [C I], CO lines and dust continuum, are significantly larger than $M_{\text{dyn}}$. Including $M_*$, the discrepancy becomes even larger:

$$8 < \frac{M_{\text{gas}} + M_*}{M_{\text{dyn}}} < 46.$$ 

The most plausible reason for this result is brightening due to the gravitational lens effect. Harris et al. (2012) reported that 11 SMGs identified by H-ATLAS at $z \sim 2.1-3.5$ are amplified by the gravitational lens effect. Harris et al. (2012) claimed that the lens magnification rate $\mu$ can be estimated from the empirical relation between the CO linewidth and luminosity for unlensed systems as

$$\mu = 3.5 \times \frac{L'(\text{CO})_{\text{apparent}}}{10^{11} \text{ K km s}^{-1} \text{ pc}^2} \left(\frac{400 \text{ km s}^{-1}}{\Delta v_{\text{FWHM}}}\right)^{1.7},$$

where $L'(\text{CO})_{\text{apparent}}$ is the apparent luminosity of CO(1−0), and $\Delta v_{\text{FWHM}}$ is the FWHM of the observed CO(1−0) spectra. Subsequently, $\mu$ of J0107a is calculated as

$$\mu(\text{J0107a}) \sim 21.$$ 

Here, we assume the linewidth ratio, $\Delta v_{\text{CO(1−0)}}/\Delta v_{\text{CO(3−2)}} = 1.15 \pm 0.06$ (Ivison et al. 2011), and derive $\Delta v_{\text{FWHM}}(\text{J0107a}) \sim 189 \text{ km s}^{-1}$, while $L'(\text{CO})_{\text{apparent}}$ is calculated with CO(4−3), which has the best S/N in our data set, and the SMG line ratio ($L'(\text{CO})_{4−3}/L'(\text{CO})_{1−0} = 0.32 \pm 0.05$; Birkin et al. 2021). In the same manner, $\mu(J0107b)$ is calculated to be $\mu(\text{J0107b}) \sim 7.9$.

Figure 10 shows the relationship between $L'(\text{CO})$ and $\Delta v_{\text{FWHM}}$ for local SFGs (Bothwell et al. 2014; Saintonge et al. 2017), high-$z$ SFGs (Daddi et al. 2010; Magdis et al. 2012; Magnelli et al. 2012; Magdis et al. 2012; Tacconi et al. 2013); and for some of these objects.

Figure 10. Plot of $L'_{\text{CO(1−0)}}$ vs. FWHM of the CO line. Red and blue circles indicate J0107a and J0107b, respectively. The data of local SFGs, which are indicated with pink downward-pointing triangles, are taken from Bothwell et al. (2014) and Saintonge et al. (2017). The data of $z \sim 1-2$ SFGs, which are indicated with green squares, are taken from Aravena et al. (2019) and Kaasinen et al. (2020). The data of millimeter-wave line emitters, which are indicated with green squares, are taken from Aravena et al. (2019) and Kaasinen et al. (2020). The data of $z \sim 2.1-3.5$ SMGs, which are indicated with green and purple upward-pointing triangles, respectively, are taken from Harris et al. (2012) and references therein. The data of millimeter-wave line emitters, which are indicated with green squares, are taken from Aravena et al. (2019) and Kaasinen et al. (2020).
the ratio of include large uncertainty. In our case, the magnification rates of J0107a from these relations, 21 and 5.9, respectively, differ by a factor of more than 3. One reason for this large difference is that both of these relations are empirical and affected by the difference of the sample. The other reason is the uncertainty in the calculation from Bothwell et al. (2013). In this calculation, the parameter C, which parameterizes the kinematics of the galaxy (Bothwell et al. 2013), depends on the galaxy’s mass distribution and velocity field, and it takes a wide range from C ≤ 1 to C ≥ 5 (Erb et al. 2006). We here adopt C = 2.1, as suggested in Bothwell et al. (2013), but it may include large uncertainty. In our case, the magnification rate from Harris et al. (2012) is reasonable, considering the consistency with the ratio of \((M_{\text{gas}} + M_{\odot})/M_{\text{dyn}}\).

Such a high magnification must result in a highly perturbed morphology of the magnified image (e.g., Tamura et al. 2015). In fact, we can find a hint of an elongated arc-like structure seen in the 0.72 resolution 887 µm continuum image (see Figure 4 (a13)), although the presence of a lens source is unclear because of contamination by the nearby bright source VV 114. This is also true in the images of Spitzer /IRAC and Chandra /ACIS-I, which are shown in Figure 1 (a) and (b). From this point of view, the intrinsic radius of J0107a might be smaller than that we adopt here. In this case, \(M_{\text{dyn}}\) of J0107a would become even smaller than the result in Section 4.2. Further, deeper, and higher-angular-resolution ALMA observations of this source will clarify the presence of a strong lens and the true size of J0107a.

6. Conclusion

We conducted analysis of ALMA band 3, 4, 6, and 7 data of J0107a and J0107b, which are serendipitously discovered millimeter-wave line-emitting galaxies in the same field as the nearby galaxy VV114. In addition, we performed kinematic modeling of J0107a and investigated its physical properties. Our findings and conclusions are as follows:

1. We identify three emission lines, CO(4–3), CO(3–2), and [CI](1–0), for each of them. In addition, we detect dust continuum emission of J0107a in bands 4, 6, and 7, and that of J0107b in bands 6 and 7.

2. By fitting the Gaussian to CO spectra, we derive the redshifts of J0107a and J0107b as \(z = 2.4666 ± 0.0002\) and \(z = 2.3100 ± 0.0002\), respectively.

3. We obtain \(M_{\text{gas}}\) of our targets with the use of [CI] line fluxes as \(M_{\text{gas}}(\text{J0107a}) = (11.2 ± 3.1) \times 10^{10} M_{\odot}\) and \(M_{\text{gas}}(\text{J0107b}) = (4.2 ± 1.2) \times 10^{10} M_{\odot}\), respectively. Moreover, using \(\alpha_{\text{CO}} = 0.8\) (Downes & Solomon 1998) and CO(1–0) luminosity, which is converted from CO(4–3), we derive \(M_{\text{gas}}\) independently as \(M_{\text{gas}}(\text{J0107a}) = (13.4 ± 1.7) \times 10^{10} M_{\odot}\) and \(M_{\text{gas}}(\text{J0107b}) = (5.0 ± 0.7) \times 10^{10} M_{\odot}\), respectively. These results are consistent with \(M_{\text{gas}}\) derived with [CI] line fluxes within uncertainties.

4. We also calculate the \(M_{\text{gas}}\) of our targets with the dust continuum emission in 1.3 mm as \(M_{\text{gas}}(\text{J0107a}) = (3.2 ± 1.6) \times 10^{11} M_{\odot}\) and \(M_{\text{gas}}(\text{J0107b}) = (9.6 ± 4.8) \times 10^{10} M_{\odot}\), respectively. This value of \(M_{\text{gas}}\) is consistent with \(M_{\text{gas}}\), which is derived with [CI] line intensity, within uncertainties.

5. We create a rotating disk model of J0107a with GaLPak3D. This model reproduces not only the moment maps of J0107a, but also the position–velocity diagram of it well. This result suggests that J0107a is likely to have a rotating disk. Using the results of this kinematic modeling, we obtain the dynamical mass of J0107a as \(M_{\text{dyn}} = (1.1 ± 0.2) \times 10^{10} M_{\odot}\).

6. We utilize the results of kinematic modeling to calculate the ratio of maximum rotation velocity \(v_{\text{max}}\) to velocity dispersion \(\sigma_{v}\), namely \(v_{\text{max}}/\sigma_{v}\), and derive \(v_{\text{max}}/\sigma_{v}\) of J0107a is quantitatively comparable to that of SMGs at similar redshifts.

7. By comparing \(M_{\text{dyn}}\) and the sum of \(M_{\text{gas}}\) and \(M_{\ast}\), we propose that J0107a is magnified by the gravitational lens effect, and detected fluxes might be magnified by a factor of more than 10. This is consistent with the excess CO luminosity of J0107a compared to the expectation from the CO linewidth.

We thank the anonymous referee for a number of insightful comments and suggestions that greatly improved the quality of this paper. Data analysis was partly carried out on the common-use data analysis computer system at the Astronomy Data Center (ADC) of the National Astronomical Observatory of Japan (NAOJ). This paper makes use of the following ALMA data: ADS/JAO.ALMA#2013.1.01057.S, #2015.1.00973.S, #2015.1.00902.S, and #2013.1.00740.S. ALMA is a partnership of ESO (representing its member states), NSF (USA), and NINS (Japan), together with NRC (Canada), MOST and ASIAA (Taiwan), and KASI (Republic of Korea), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/NRAO and NAOJ. This work was supported by JSPS KAKENHI grant No. JP17H06130 and by the NAOJ ALMA Scientific Research grant No. 2017-06B. F. E. is supported by JSPS KAKENHI grant No. 17K14259. D.E. acknowledges support from a Beatriz Galindo senior fellowship (BG20/00224) from the Spanish Ministry of Science and Innovation. D. I. is supported by JSPS KAKENHI grant No. 21H01133.

Appendix

Cross-correlations between the GaLPak3D Results

For a kinematic modeling of the galactic disk of J0107a, we utilize GaLPak3D to estimate some physical parameters. Figure 11 shows cross-correlations between the result of 5 parameters which is estimated by the modeling with GaLPak3D.
The cross-correlation plot of a Markov chain in GalPaK modeling with an initial inclination angle of $i = 60^\circ$. We use the last 12,000 iteration data of a total 20,000 iterations to avoid using the data before MCMC burn-in. The gray dots indicate individual iteration data, and the density of these data is presented with contours. The solid and dashed lines indicate the average (50th percentile) and $2\sigma$ width ($2.5\text{th}$ and $97.5\text{th}$ percentiles) of each parameter, respectively.
