(Dated: May 5, 2014)

Hybrid-kinetic numerical simulations of firehose and mirror instabilities in a collisionless plasma are performed in which pressure anisotropy is driven as the magnetic field is changed by a persistent linear shear $S$. For a decreasing field, it is found that mostly oblique firehose fluctuations grow at ion Larmor scales and saturate with energies $\propto S^{1/2}$; the pressure anisotropy is pinned at the stability threshold by particle scattering off microscale fluctuations. In contrast, nonlinear mirror fluctuations are large compared to the ion Larmor scale and grow secularly in time; marginality is maintained by an increasing population of resonant particles trapped in magnetic mirrors. After one shear time, saturated order-unity magnetic mirrors are formed and particles scatter off their sharp edges. Both instabilities drive sub-ion-Larmor-scale fluctuations, which appear to be kinetic-Alfvén-wave turbulence. Our results impact theories of momentum and heat transport in astrophysical and space plasmas, in which the stretching of a magnetic field by shear is a generic process.

PACS numbers:
of the perpendicular and parallel pressures is
\[
\frac{p_{\perp}}{p_{\parallel}} = \frac{\int d^3v \mu B f_i}{\int d^3v m_i v_{\parallel i}^2 f_i} = \left[ 1 - \frac{2 B_z B_{0\parallel}}{B_0^2} s t + \frac{B_z^2}{B_0^2} (s t)^2 \right]^{3/2},
\]
where the subscript ‘0’ denotes initial values.

Method of solution. We solve Eqs. 1–5 using the second-order–accurate particle-in-cell code PEGASUS [29]. We normalize magnetic field to \(B_0\), velocity to the initial Alfvén speed \(v_{0A} = B_0/\sqrt{4\pi m_i n_0}\), time to the inverse of the initial ion gyrofrequency \(\Omega_{0i} = Z e B_0/m_i c\), and distance to the initial ion skin depth \(d_{0i} = v_{0A}/\Omega_{0i}\). The ion Larmor radius \(\rho_i = \beta^{3/2}\), where \(\beta = 8\pi n_i T_i/B_0^2\).

\(N_p\) particles are drawn from a Maxwellian distribution with \(\beta_0 = 200\) and placed on a 2D grid \(N_x \times N_y = 1152^2\) cells spanning \(L_x \times L_y = 1152^2\). The electrons are Maxwellian and gyrotropic with \(T_e/T_0 = 1\). A \(\delta f\) method reduces the impact of discrete-particle noise on the moments of \(f_i\) [30, 31]. Orbital advection updates the particle positions and magnetic field due to the background shear [32]. The boundary conditions are shearing-periodic: \(f(x, y) = f(x \pm L_x, y \mp S L_x t)\). We scan \(S = (1, 3, 10, 30) \times 10^{-4}\). These parameters guarantee a healthy scale separation between the grid scale, the ion Larmor radius, the wavelengths of the instabilities, and the box size. In what follows, \(\langle \cdot \rangle\) denotes a spatial average over all cells.

Firehose instability. We choose \(N_i = 1024 N_e N_y\) and set \(B_0 = (2\pi + 3\hat{y})/\sqrt{13}\), so that \(\langle B_y \rangle = \langle B_x \rangle\) at \(S = 1/2\). As \(B\) decreases, adiabatic invariance drives \(p_{\perp}/p_{\parallel} < 1\) (Eq. 6), with plasma becoming firehose unstable when \(\Lambda_t \equiv 1 - p_{\perp}/p_{\parallel} - 2/\beta_{\parallel} > 0\). Exponentially growing, Alfvénically polarized \(\langle |\delta B_{\parallel}| \gg |\delta B_{\perp}|\), oblique modes with growth rate \(\gamma \simeq k_{\parallel} \rho_i (\Lambda_t/2)^{1/2}\) and \(k_{\parallel} \rho_i \approx k_{\perp} \rho_i \approx 0.4\) then appear (Fig. 1b; cf. [33, 34]). Fig. 2 shows their spatial structure. \(\Lambda_t\) continues to grow, driven by shear \((\Lambda_t \sim S t;\) Fig. 1b), until the perturbations become large enough to reduce the pressure anisotropy to its marginally stable value \((\Lambda_t \to 0)\).

It has been proposed [24, 35] that they do this by canceling the rate of change of the mean field: \((1/2) d|\delta B_{\perp}|^2/dt \approx -d \ln (|B|)/dt \sim S\), giving rise to secular evolution, \(\langle |\delta B_{\perp}|^2 \rangle \sim S t\). Matching \(\gamma \sim \Lambda_t^{1/2} \sim (S t)^{1/2}\) with the rate of growth in the secular phase \((\gamma \sim 1/t)\), we find \(\langle |\delta B_{\perp}|^2 \rangle \sim S t \sim \Lambda_t \sim S t^{2/3}\) at the transition from linear to nonlinear evolution (cf. [36, 37]; “quasi-linear saturation”). This scenario is indeed what we observe: the evolution of \(\langle |\delta B_{\perp}|^2 \rangle\) and \(\Lambda_t\) is shown in Fig. 1b note the \(\langle \Lambda_t \rangle_{\text{max}} \sim S t^{2/3}\) (inset in Fig. 1b). To test the idea [24, 37] that, during the secular phase, the average \(B\) seen by particles streaming along the field is constant, we plot in Fig. 2 a representative particle’s \(\mu\) and \(B\) (evaluated at the particle’s position) for \(S = 3 \times 10^{-4}\). During the secular phase, the particle nearly conserves \(\mu\) and \(B \approx \text{const}\) along its trajectory, as expected.

However, this secular growth is not sustainable: the magnetic fluctuation energy saturates at a low level \(\propto S t^{1/2}\) (inset of Fig. 1b) in a state of firehose turbulence. During this saturated state, particles scatter off fluctuations with \(k_{\parallel} \rho_i \sim 1\). \(\mu\) conservation is broken, and \(B\) decreases at a rate approaching \(-d \ln (|B|)/dt \sim S\) (Fig. 3). The production of pressure anisotropy is no longer adiabatically tied to the rate of change of the magnetic field and marginality \((\Lambda_t \approx 0)\) is maintained independently of \(S\) via anomalous particle scattering. We calculate the mean scattering rate \(\nu_{\text{scatt}}\) by tracking 4096 randomly selected particles, constructing a distribution of times taken by each to change its \(\mu\) by a factor of \(e\), and taking the width of the resulting exponential function to be \(\nu_{\text{scatt}}^{-1}\). In a collisional, incompressible plasma without heat flows, the pressure anisotropy would be \(p_{\perp}/p_{\parallel} = 1 - (3/\nu) d \ln (|B|)/dt\), where \(\nu\) is collision rate [24, 38]. The effective scattering rate

\(\nu_{\text{scatt}}\) (Fig. 3) provides a check on the consistency of this scenario and is a measure of the rate of energy transfer to fluctuations. The fluctuation energy, which initially grows, is limited by the rate at which it is dissipated via \(\nu_{\text{scatt}}\). This transient behavior is consistent with the observed dynamics, suggesting that the firehose instability saturates at a low level due to energy dissipation via particle scattering. The anisotropy then becomes marginally stable, and the system evolves toward a saturated state.
needed to maintain $\Lambda_{\text{f}} = 0$ at saturation would then be $\nu_{\text{sat}} \equiv -3(\beta_{||})_{\text{sat}}(d\ln \langle B^2 \rangle /dt)_{\text{sat}} \sim S\beta$. Remarkably, we find $\nu_{\text{sat}} \approx \nu_{\text{f}}$ in the saturated state (Fig. 4).

**Mirror instability.** We choose $N_y = 625N_xN_y$ and set $B_0 = (2\hat{x} - \hat{y})/\sqrt{3}$, so that $\langle B_y \rangle = -\langle B_x \rangle$ at $St = 1/2$. As $B$ increases, adiabatic invariance drives $p_{\perp}/p_\parallel > 1$ (Eq. 9), with plasma becoming mirror unstable when $\Lambda_m \equiv p_{\perp}/p_\parallel - 1 - 1/\beta_{||} > 0$ [11]. Near threshold, linearly growing perturbations have $\gamma \sim \Lambda_m^2$, $k_{||}\rho_i \sim \Lambda_m$, and $k_{\perp}\rho_i \sim \Lambda_m^{1/2}$ [39]—they grow slower than the firehose, are more elongated in the magnetic-field direction, and have $\delta B_{||} \gg \delta B_{\perp}$. Fig. 5 shows their spatial structure.

The saturation scenario is analogous to the firehose: $\Lambda_m$ continues growing (Fig. 5b) until the mirror perturbations are large enough to drive $\Lambda_m \to 0$, at which point the perturbations’ exponential growth gives way to secular evolution with $\langle \delta B_{||}^2 \rangle \propto t^{4/3}$ (Fig. 5a, discussed below). As $\Lambda_m \to 0$, the dominant modes shift to longer wavelengths ($k_{||}\rho_i \ll 1$) and become more elongated in the magnetic-field direction. Excluding the (non-asymptotic) $S = 10^{-3}$ case, this secular phase appears to be universal, lasting until $\delta B/B_0 \sim 1$ at $St \gtrsim 1$, independently of $S$. The final saturation is caused by particle scattering off sharp $\delta B_{||} = 1$, $k_{||}\rho_i \sim 1$ bends in the magnetic field, which occur at the boundaries of the magnetic mirrors.

As foreseen by [40, 42], trapped particles play a crucial role in the nonlinear evolution. Following [25, 33], we expect the pressure anisotropy to be pinned at marginal by an increasing fraction ($\sim|\delta B_{||}|^{1/2}$) of particles becoming trapped in magnetic mirrors, thereby sampling regions where the increase of the mean field is compensated by the decrease in the perturbed field, viz.

$$
-\overline{d(\delta B_{||})/dt} \sim \overline{d(\delta B_{||}^{1/2})/dt} \sim \overline{d\ln \langle B \rangle /dt} \sim S,
$$

where the overbar denotes averaging along particle trajectories (i.e. bounce-averaging for trapped particles). It follows that $\langle \delta B_{||}^2 \rangle \sim (St)^{4/3}$, as is indeed seen in Fig. 5b.

Fig. 6 displays $\mu$, $B$, and $v_{||}$ for representative passing and trapped particles in the simulation with $S = 3 \times 10^{-4}$. 

---

**FIG. 3:** Evolution of $\mu$ and $B$ for a representative particle in the firehose simulation with $S = 3 \times 10^{-4}$.

**FIG. 4:** Mean scattering rate $\nu_{\text{scatt}}$ for (left) firehose and (right) mirror in the secular (crosses) and saturated (plus signs) phases versus $S\beta_0$. The collision rates required to maintain marginal stability in the saturated phase, $\nu_{\text{f}}$ and $\nu_{\text{m}}$, respectively, are shown for comparison. See text for definitions.

**FIG. 5:** Evolution of mirror instability versus $S$. (a) Energy in parallel fluctuations of the magnetic field, $\langle \delta B_{||}^2 \rangle$. (b) Mirror stability parameter, $\langle \Lambda_m \rangle$, whose maximum value $\propto S^{3/2}$.

**FIG. 6:** Spatial structure of the mirror instability with $S = 3 \times 10^{-4}$. $\delta B_{||}/B_0$ and (last panel) re-scaled $\delta n_i/n_{i0}$ are shown (color) with magnetic-field lines in the shearing plane.
In the linear phase, both particles conserve $\mu$ very well. During the secular phase ($St \simeq 0.2\text{-}1.4$), one of the particles becomes trapped and bounces while nearly conserving $\mu$; $B \simeq \text{const}$ along its path, despite the growing mean field. The other remains passing, with $\delta B/|B| \simeq 0$. At the end of the secular phase, the trapped particle scatters out of the mirror and becomes passing.

The mean scattering rates $\nu_{\text{scatt}}$ are different for the trapped and passing populations. During the secular phase, the trapped particles ($\sim 70\%$ towards the end of the secular phase) have $\nu_{\text{scatt}} \approx 0.002$ (Fig. 7), while the passing particles have $\nu_{\text{scatt}} \approx 0.3$. Excepting the $S = 10^{-3}$ case, these values are independent of $S$, indicating that particle scattering is irrelevant for $S \lesssim 1$ and $S \ll 1$. At saturation ($St \gtrsim 1$), the percentage of trapped particles drops to $\sim 30\%$ (with $\nu_{\text{scatt}} \approx 0.004$) and the total $\nu_{\text{scatt}} \approx \nu_m$, where $\nu_m \equiv 3/\text{dln}$ $|\langle B \rangle|/\text{dln}$ $\delta B$ is the collisionality required to maintain $\Lambda_m = 0$ at saturation (by the same argument as in the firehose discussion).

**Firehose- and mirror-driven turbulence.** The saturated state of both instabilities is characterized by super-Larmor-scale driving and sub-Larmor-scale fluctuations. Fig. 6 shows 1D magnetic fluctuation spectra for firehose and mirror at saturation versus $k_{||}$ and $k_{\perp}$ for $S = 3 \times 10^{-4}$. Energy is injected at successively larger scales as marginality is approached [cf. 21,37] and several power laws are established. Firehose modes with $k_{\rho_B} < 1$ satisfy $|\delta B_{\perp}||k_{\perp}|^2 \propto k_{\perp}^{-3}$, a spectrum reminiscent of the collimation required to maintain $\Lambda_m = 0$ at saturation (by the same argument as in the firehose discussion). For parallel-firehose turbulence [24], Mirror modes with $k_{\rho_B} < 1$ satisfy $|\delta B_{||}|k_{||}|^2 \propto k_{||}^{-11/3}$. This scaling is obtained by an argument analogous to that proposed in [24]: seek a power-law spectrum, $|\delta B_{||}|k_{||}|^2 \propto k_{||}^{-\alpha}$; estimate $\gamma_{\text{peak}} \sim \Lambda_m^{-1/2} \approx 1/t$ and $k_{||,\text{peak}} \sim \Lambda_m^{-1/2} \approx 1/t^{1/2}$ for the energy-containing mode in the secular phase; recall $\sum k_{||}|\delta B_{||}|k_{||}|^2 \propto (St)^{4/3}$, and demand that this be consistent with $\sum k_{||}|\delta B_{||}|k_{||}|^2 \approx k_{||,\text{peak}}^{-1-\alpha} \approx t^{-(1-\alpha)/2}$. This procedure yields $\alpha = 11/3$. Finally, the $k$-shell-averaged density fluctuation spectra (Fig. 7c) follows $|\delta B_{||}|^2$, as expected for pressure-balanced mirrors.

Both spectra indicate that energy is removed at sub-Larmor scales by what appears to be a turbulent cascade, whose spectral slope and polarization of the fluctuations ($\delta n_i \sim \beta^{-1} |\delta B_{||}|$, [13,44]) approximately matches observations of KAW turbulence in gyrokinetic simulations [45] and the solar wind [46–48], as well as of “mirror turbulence” in the magnetosheath [49]. This marks the first time in a simulation of mirror or firehose turbulence that a KAW cascade has been observed. Nevertheless, we caution that our simulations were performed in 2D, a proper study of this cascade requires 3D geometry [43,45,50].

**Summary.** We have presented numerical simulations of firehose and mirror instabilities driven by a changing magnetic field in a local shear flow. Both instabilities start in the linear regime with exponential growth, a process that is well understood analytically. The theoretical expectation, that after linear saturation the growth becomes secular as the pressure anisotropy is persistently driven [24,25,35], is borne out by our simulations. For the firehose, the marginal state is initially achieved via $\mu$-conserving changes in the magnetic field, but is subsequently maintained (independent of $S$) by particle scattering off $k_{||,\rho_B} \sim 1$ fluctuations. For the mirror, marginal stability is achieved and maintained during the secular phase by particle trapping in magnetic mirrors. Saturation occurs once $\delta B/B_0 \sim 1$ at $St \gtrsim 1$ via particle
scattering off the sharp ends of the mirrors. For both instabilities, the mean scattering rate at saturation adjusts to maintain marginal stability, effectively reducing the viscosity to \( v_{th}^2/\nu_{\text{scatt}} \sim v_{A,\text{sat}}^2/S \).

Support for MWK was provided by NASA through Einstein Postdoctoral Fellowship Award Number PF1-120084, issued by the Chandra X-ray Observatory Center, which is operated by the Smithsonian Astrophysical Observatory for and on behalf of NASA under contract NAS8-03060. The Texas Advanced Computer Center at The University of Texas at Austin provided HPC resources under grant numbers TG-AST090105 and TG-AST130002, as did the PICSciE-OIT TIGRESS High Performance Computing Center and Visualization Laboratory at Princeton University. This work used the Extreme Science and Engineering Discovery Environment (XSEDE), which is supported by NSF grant OCI-1053575. MWK and AAS thank Merton College, Oxford and the Max-Planck/Princeton Center for Plasma Physics for travel support. [51] Technically, this instability parameter is for cold electrons [39], but it is close enough to reality for simplicity to outweigh precision in our treatment.
[52] This is consistent with the fraction of trapped particles being $f_T = (1 - B_{\text{min}}/B_{\text{max}})^{1/2}$. For $B_{\text{max}}/B_{\text{min}} \simeq 1.8$ near the end of the secular phase (see Fig. 6), $f_T \simeq 0.66$.
