ABSTRACT
White dwarfs inspiralling into black holes of mass $M_{\text{BH}} \gtrsim 10^5 M_\odot$ are detectable sources of gravitational waves in the Laser Interferometer Space Antenna (LISA) band. In many of these events, the white dwarf begins to lose mass during the main observational phase of the inspiral. The mass-loss starts gently and can last for thousands of orbits. The white dwarf matter overflows the Roche lobe through the $L_1$ point at each pericentre passage and the mass-loss repeats periodically. The process occurs very close to the black hole and the released gas can accrete, creating a bright source of radiation with luminosity close to the Eddington limit, $L \sim 10^{43}$ erg s$^{-1}$. This class of inspirals offers a promising scenario for dual detections of gravitational waves and electromagnetic radiation.

Key words: black hole physics – gravitational waves – white dwarfs.

1 INTRODUCTION

One of the goals of the Laser Interferometer Space Antenna (LISA) mission is to detect gravitational waves from compact stellar objects spiralling into massive black holes, a class of events called extreme-mass-ratio inspirals (EMRIs; e.g. Hils & Bender 1995; Barack & Cutler 2004; Gair et al. 2004; see Hughes 2009 and Sathyaprakash & Schutz 2009 for recent reviews). Of particular interest are sources of coincident gravitational and electromagnetic radiation. Besides providing unique information on the nature of the event, such dual detections will lead to a new version of Hubble diagram that is based on the gravitational distance measurements (e.g. Bloom et al. 2009; Phinney 2009).

Inspirals into black holes of masses $M_{\text{BH}} \sim (10^5-10^6) M_\odot$ produce gravitational waves in the frequency band where LISA is most sensitive. Normal stars are tidally disrupted well before they approach such black holes, and therefore discounted as possible LISA sources (however, see Freitag 2003). Inspirals of compact objects are guaranteed sources of gravitational waves; however, most of them are not promising for dual detections. In particular, stellar mass black hole or neutron star inspirals are not expected to generate bright electromagnetic signals. Only inspiralling white dwarfs (WDs) offer a possibility for dual detection (Menou, Haiman & Kocsis 2008; Sesana et al. 2008). WDs can be tidally disrupted very close to the black hole and then could create a transient accretion disc with Eddington luminosity.

Estimated EMRI rates are high enough for observations with LISA (e.g. Phinney 2009). The expected fraction of WD inspirals among all EMRIs depends on the degree of mass segregation in galactic nuclei, which favours stellar mass black holes over WDs in the central cluster. The abundance of WDs also depends on the details of stellar evolution, which are not completely understood. A fraction of WD inspirals as large as $\sim 10$ per cent has been suggested (e.g. Hopman & Alexander 2006a).

The orbital parameters of WD inspirals are also uncertain. EMRIs form when a compact object is captured on to a tight orbit whose evolution is controlled by gravitational radiation rather than random interactions with other stars in the central cluster around the massive black hole. Two main channels exist for EMRI formation: capture of single stars and capture of binary systems (e.g. Hils & Bender 1995; Sigurdsson & Rees 1997; Ivanov 2002; Gair et al. 2004; Hopman & Alexander 2005; Miller et al. 2005; Hopman & Alexander 2006a; Hopkins 2009). In the single-capture scenario, the shrinking orbit can retain a significant eccentricity until the end of inspiral. In contrast, the binary-capture scenario leads to nearly circular orbits (Miller et al. 2005).

In this Letter, we focus on WD inspirals that are not completed because the star is tidally disrupted before its orbit becomes unstable. We argue that the WD begins to lose mass very gently and, for thousands of orbital periods, this process resembles accretion through the $L_1$ point in a binary system rather than a catastrophic disruption. This offers a possibility of simultaneous observation of the inspiral by LISA and traditional, optical and X-ray telescopes. Previous work on tidal deformation of a WD orbiting a massive black hole focused on two extreme regimes: (i) weak deformation was studied analytically using perturbation theory (e.g. Rathore, Blandford & Broderick 2005; Ivanov & Papaloizou 2007) and (ii) strong deformation leading to immediate disruption was simulated numerically (e.g. Kobayashi et al. 2004; Rosswog, Ramirez-Ruiz...
The orbital parameters gradually evolve as a result of gravitational effects beyond the quasi-static limit (e.g. Ritter 1988). We will consider a WD orbit with semimajor axis $a$ and eccentricity $e$. The orbital parameters gradually evolve as a result of gravitational radiation (Peters 1964),

$$\ddot{a} = -\frac{64}{5} \frac{G^3 M M_{\text{BH}}^2}{c^5 a^3 (1-e^2)^{5/2}} \left(1 + \frac{73}{24} e^2 + \frac{37}{96} e^4\right),$$

$$\ddot{e} = -\frac{304}{15} \frac{G^3 M M_{\text{BH}}^2}{c^5 a^3 (1-e^2)^{5/2}} \left(1 + \frac{121}{304} e^2\right) e,$$

where $M$ is the mass of the WD and dot denotes the time derivative of the secular evolution (averaged over the orbit). Both $a$ and $e$ slowly decrease with time. The fractional change of the pericentre radius $r_p = a(1-e)$ in one orbital period $P = 2\pi (a^3/GM_{\text{BH}})^{1/2}$ is

$$\alpha \equiv -\frac{\dot{r}_p}{r_p} = \frac{128 \pi G^2 M_{\text{BH}}^2 M}{5 c^3 r_p^{5/2}} \left(1 - \frac{73}{128} e^2 + \frac{37}{304} e^4\right) (1+e)^{7/2}.$$  

For the typical parameters of the problem considered in this Letter, $\alpha \sim 10^{-5}$. Two inaccuracies in the above formulae should be noted: (i) equations (1)–(3) are valid only if $r_p \gg GM_{\text{BH}}/c^2$. They become approximate during the most interesting phase of the inspiral when $r_p$ is only a few $2GM_{\text{BH}}/c^2$. (ii) The equations neglect the effects of mass-loss on the evolution of the orbit.  

The mass-loss begins when the tidal acceleration created by the black hole at the WD surface, $(GM_{\text{BH}}/r_p^2) R$, becomes comparable to $GM/R^2$, where $R$ is the radius of the WD. A similar condition is the onset of mass transfer in synchronous binary systems is that the donor star fills its Roche lobe. In the more complicated case of eccentric non-synchronous binary systems, mass transfer may be approximately described using an instantaneous effective Roche lobe (Sekipnys, Willemis & Kalgogora 2007), neglecting all the effects beyond the quasi-static limit (e.g. Ritter 1988). We will use the following approximate condition for the mass-loss onset: 

$$R > R_t = \gamma r_p \left(\frac{M}{M_{\text{BH}}}\right)^{1/3},$$

where $R$ is the radius of the unperturbed star before it experiences any tidal deformation and $\gamma$ is a numerical constant. The exact value of $\gamma$ depends on the mass ratio $M/M_{\text{BH}}$ and the orbital parameters $a$ and $e$. Even more importantly, it also depends on the rotation of the WD and the history of its tidal heating, none of which is known. If $R_t$ is interpreted as the effective Roche lobe studied by Sekipnys & Hix 2009). The regime considered in this Letter is different from both cases explored previously. It involves an extended phase of strong deformation with small mass-loss, which we call ‘tidal stripping’ below. The mass of the WD remains almost unchanged during this phase and continues to emit gravitational waves. Even a small orbital eccentricity, e.g. $e = 0.01$, implies that tidal stripping occurs only near the pericentre of the orbit, during a small fraction of each orbital period. Thus, the mass-loss is expected to be periodic, possibly leading to a periodic electromagnetic signal from the inspiral.

2 TIDAL STRIPPING

2.1 Onset of mass-loss

Consider a WD orbit with semimajor axis $a$ and eccentricity $e$. The orbital parameters gradually evolve as a result of gravitational radiation (Peters 1964),

$$\ddot{a} = -\frac{64}{5} \frac{G^3 M M_{\text{BH}}^2}{c^5 a^3 (1-e^2)^{5/2}} \left(1 + \frac{73}{24} e^2 + \frac{37}{96} e^4\right),$$

$$\ddot{e} = -\frac{304}{15} \frac{G^3 M M_{\text{BH}}^2}{c^5 a^3 (1-e^2)^{5/2}} \left(1 + \frac{121}{304} e^2\right) e,$$

where $M$ is the mass of the WD and dot denotes the time derivative of the secular evolution (averaged over the orbit). Both $a$ and $e$ slowly decrease with time. The fractional change of the pericentre radius $r_p = a(1-e)$ in one orbital period $P = 2\pi (a^3/GM_{\text{BH}})^{1/2}$ is

$$\alpha \equiv -\frac{\dot{r}_p}{r_p} = \frac{128 \pi G^2 M_{\text{BH}}^2 M}{5 c^3 r_p^{5/2}} \left(1 - \frac{73}{128} e^2 + \frac{37}{304} e^4\right) (1+e)^{7/2}.$$  

For the typical parameters of the problem considered in this Letter, $\alpha \sim 10^{-5}$. Two inaccuracies in the above formulae should be noted: (i) equations (1)–(3) are valid only if $r_p \gg GM_{\text{BH}}/c^2$. They become approximate during the most interesting phase of the inspiral when $r_p$ is only a few $2GM_{\text{BH}}/c^2$. (ii) The equations neglect the effects of mass-loss on the evolution of the orbit.  

The mass-loss begins when the tidal acceleration created by the black hole at the WD surface, $(GM_{\text{BH}}/r_p^2) R$, becomes comparable to $GM/R^2$, where $R$ is the radius of the WD. A similar condition is the onset of mass transfer in synchronous binary systems is that the donor star fills its Roche lobe. In the more complicated case of eccentric non-synchronous binary systems, mass transfer may be approximately described using an instantaneous effective Roche lobe (Sekipnys, Willemis & Kalgogora 2007), neglecting all the effects beyond the quasi-static limit (e.g. Ritter 1988). We will use the following approximate condition for the mass-loss onset: 

$$R > R_t = \gamma r_p \left(\frac{M}{M_{\text{BH}}}\right)^{1/3},$$

where $R$ is the radius of the unperturbed star before it experiences any tidal deformation and $\gamma$ is a numerical constant. The exact value of $\gamma$ depends on the mass ratio $M/M_{\text{BH}}$ and the orbital parameters $a$ and $e$. Even more importantly, it also depends on the rotation of the WD and the history of its tidal heating, none of which is known. If $R_t$ is interpreted as the effective Roche lobe studied by Sekipnys & Hix 2009). The regime considered in this Letter is different from both cases explored previously. It involves an extended phase of strong deformation with small mass-loss, which we call ‘tidal stripping’ below. The mass of the WD remains almost unchanged during this phase and continues to emit gravitational waves. Even a small orbital eccentricity, e.g. $e = 0.01$, implies that tidal stripping occurs only near the pericentre of the orbit, during a small fraction of each orbital period. Thus, the mass-loss is expected to be periodic, possibly leading to a periodic electromagnetic signal from the inspiral.

2.2 Estimate for mass-loss in one orbital period

As the star begins to lose mass, it continues to do so repeatedly: at each pericentre passage the star overflows the Roche lobe for a short time. The hydrodynamics of the surface layers of the tidally stripped star is complicated. It is clear however that the mass lost in one pericentre passage, $\delta M$, will be tiny for the initial mass-loss

$\delta M$ be the mass lost in one orbit. The maximum correction to $a$ is $-\delta M/M$, and it is significant only when $\delta M$ exceeds $aM$. Section 2.3 suggests that the value of $a$ is unimportant at this stage as the evolution becomes controlled by the mass-loss itself, not the drift of the pericentre.

Let $\delta M$ be the mass lost in one orbit. The maximum correction to $a$ is $-\delta M/M$, and it is significant only when $\delta M$ exceeds $aM$. Section 2.3 suggests that the value of $a$ is unimportant at this stage as the evolution becomes controlled by the mass-loss itself, not the drift of the pericentre.
episodes when the star surface barely touches the Roche lobe. The natural small parameter in the problem is \( \Delta/R = (R - R_0)/R \). The onset of mass-loss is defined by \( \Delta \equiv R - R_0 \ll R \), and we assume that the dependence of \( \delta M \) on \( \Delta/R \ll 1 \) can be expanded in a series whose leading term has the form

\[
\frac{\delta M}{M} = A \left( \frac{\Delta}{R} \right)^\psi, \quad \Delta \equiv R - R_0 \ll R,
\]

where \( A \) is a numerical factor. For illustration, consider a toy model. Suppose that after the pericentre passage the star loses the surface shell \( \Delta \ll R \) whose mass is estimated using the structure of the unperturbed star,

\[
\delta M = 4\pi R^2 \int_0^{\Delta} \rho(z) \, dz.
\]

Here \( z \) is the depth measured inward from the surface and \( \rho(z) \) is the mass density of the unperturbed star at depth \( z \). For simplicity, let us assume the polytropic equation of state in the surface layer \( P = K \rho^{\gamma} \) with \( \gamma = 5/3 \), the same as in the deeper region where electrons become degenerate. \( P \) and \( \rho \) change continuously between the degenerate and non-degenerate regions, and therefore \( K \) in the surface layers must be the same as for non-relativistic degenerate electron gas,

\[
K = \frac{1}{20} \left( \frac{3}{\pi} \right)^{2/3} \frac{h^2}{m_e(\mu_e m_p)^{2/3}},
\]

where \( \mu_e \approx 2 \) is the mean molecular weight per electron. The hydrostatic balance \( dP/dz = \rho GM/R^2 \) gives

\[
\rho(z) = \frac{2GM^2}{5KR^2} \left( \frac{z}{R} \right)^{3/2},
\]

and evaluating the integral in equation (8) one finds \( \delta M/M = A(\Delta/R)^\psi \) with

\[
\psi = \frac{5}{2}, \quad A \approx 6.1 \left( 1 - \frac{M}{M_{\text{Ch}}} \right)^{3/2}.
\]

In this toy model, \( \delta M = (6/5)\rho(\Delta)/\rho(\Delta/R) \), where \( \rho = 3M/4\pi R^2 \). The small factor \( (\Delta/R)^\psi \ll 1 \) in \( \delta M \) results from the small thickness of the surface layer \( \Delta \) and the small density of this layer, \( \rho(\Delta)/\rho \sim (\Delta/R)^{3/2} \).

Additional factors may enter a more realistic model. The duration of the mass-loss episode \( \delta t \) may be so short that only a fraction of the \( \Delta \)-layer is lost. \( \delta t \) likely scales with some power of \( \Delta/R \). One could formulate a time-dependent model for the mass-loss episode by evaluating \( \delta t \) along the orbit around the pericentre (instead of just one point \( r_0 \)). If one assumes that the mass-loss episode occurs where \( R < R_0 \), then \( \delta t \sim (\Delta/R)^{1/2} \), where \( \tau \) is the sound-crossing time of the star. A complete hydrodynamical model is three-dimensional as the mass-loss is asymmetric: gas will flow through the \( L_1 \) point, as happens in close binary systems. The flow velocity may be comparable to the sound speed in the outer layers of the star (which is smaller than the sound speed in its interior). Perhaps future hydrodynamical calculations will give the duration of the mass-loss episode and the resulting \( \psi \), \( A \) and \( \delta M \). We do not know the exact values of \( \psi \) and \( A \) and keep them as parameters. The illustrative numerical example shown below assumes \( \psi \) and \( A \) given in equation (11).

From equations (4) and (6) one finds

\[
\frac{\Delta}{R} = 1 - \frac{R_0}{R} = 1 - \frac{r_0}{r_0} \left( \frac{M}{M_0} \right)^{2/3} \left( \frac{M_{\text{Ch}} - M}{M_{\text{Ch}} - M_0} \right). \tag{12}
\]

For the first mass-loss episode, \( M = M_0 \) and \( r_0/M_0 \sim 1 - \alpha \), which implies \( \Delta/R \sim \alpha \sim 10^{-2} \). Equation (12) shows that \( \Delta \) grows with each passage of the pericentre as \( r_0 \) decreases (due to gravitational radiation) and \( M \) decreases (due to mass-loss).

### 2.3 Evolution of mass-loss over many orbits

\( N \) orbits after the star reached \( r_0 \), the pericentre radius is given by

\[
\frac{r_0}{r_0} \approx 1 - \alpha N, \quad \alpha N \ll 1,
\]

where \( \alpha \) is given by equation (3). Here we assumed that \( r_0 \) decreases by \( \alpha r_0 \) in each orbit, neglecting the effect of mass-loss on the orbit (which is likely to be a poor approximation at late stages of mass-loss, e.g. Bildsten & Cutler 1992).

Let \( x \) be the mass fraction of the star that has been lost over \( N \) orbits,

\[
x = \frac{M_0 - M}{M_0}.
\]

As long as \( x \ll 1 \), one can expand \( \Delta \) in \( x \) and \( \alpha N \) and keep only the leading linear terms,

\[
\Delta \approx \Delta \frac{\Delta}{R} \approx \alpha N + B \psi, \quad B = \frac{2}{3} - \beta \frac{M_0}{M_{\text{Ch}} - M_0}.
\]

The term \( \alpha N \) describes the change in \( R_0/R_0 \) due to the decreasing \( r_0 \) while the small changes in \( M \) and \( R \) are neglected. The term \( B \psi \) describes the effect of decreasing \( M \) on \( R_0 \) and \( R \) while the small drift of the pericentre is neglected.

It is convenient to treat \( N \gg 1 \) as a continuous variable and describe the mass-loss by the differential equation \( dM/dN = -\delta M \). Then substitution of equation (15) to equation (7) gives the differential equation for \( x(N) \),

\[
\frac{dx}{dN} = A(\alpha N + Bx)^{\psi}.
\]

One can see from this equation that there are two stages of mass-loss: (i) \( Bx \ll \alpha N \) and (ii) \( Bx \gg \alpha N \). Assuming \( \psi > 1 \), we find the solutions for the two regimes,

\[
x \approx A \left( \frac{\psi + 1}{A} \right)^{1/\psi} \alpha^{N/\psi + 1}, \quad N < N_1,
\]

\[
x \approx \left[ (\psi - 1)B^{\psi}(N_0 - N) \right]^{1/(1-\psi)}, \quad N > N_1.
\]

Equation (18) applies only as long as \( x \ll 1 \); however, it gives an estimate for the number of orbits to complete disruption \( N_1 \). The values of \( N_1 \) and \( N_0 \) can be evaluated by matching \( x \) and \( dx/dN \) for the two solutions at \( N = N_1 \),

\[
N_1 = \left( \frac{\psi + 1}{A} \right)^{1/\psi} \alpha^{(1-1/\psi)}/B.
\]

\[
N_1 - N_1 = \frac{1}{\psi^2 - 1}.
\]

At \( N < N_1 \), the growth of \( x \) is caused by the decrease in \( r_0 \) at practically unchanged mass and radius of the star. After \( N_1 \) orbits, the growth of \( x \) accelerates as it is now controlled by the decreasing \( M \) (and increasing \( R \)), while the change in \( r_0 \) has a negligible effect. Equations (17) and (18) imply that \( \delta M \propto N^{\psi} \) for \( N < N_1 \) and \( \delta M \propto (N_0 - N)^{\psi/(\psi-1)} \) for \( N > N_1 \).

For example, consider the toy model described by equation (11). In this case, \( N_1 \sim \alpha^{-3/5} \sim 10^4 \) and \( N_1 - N_1 = (4/21)N_1 \). The mass fraction lost after \( N_1 \) orbits is \( x(N_1) \sim \alpha N_1/B \sim 2^{2/5} \sim 10^{-2} \). The detailed behaviour of \( x(N) \) in the toy model is shown in Fig. 2 for a WD with initial mass \( M_0 = 0.6M_{\odot} \). The figure shows the solution of equation \( dx/dN = A(\Delta/R)^{\psi} \), given by equation (12).
The standard picture of EMRI envisions an orbit that gradually ralling into a black hole with initial mass $M_0 = 0.6M_\odot$, orbiting a black hole with $M_{BH} = 10^5 M_\odot$; the orbit has eccentricity $e = 0.9$. The horizontal axis shows ‘time during mass transfer’, which increases only when $M \neq 0$. The area under each peak is the mass lost per pericentre passage; it follows a power law with the number of orbits left to complete disruption, $\delta M \propto (N_* - N)^{-1.8}$, close to the results of Section 2.3.

To summarize, the tidal stripping begins very gently because the pericentre of the orbit drifts inward slowly, by a tiny fraction $\sim 10^{-5}$ in one orbital period. This leads to many repeated episodes of small mass-loss. The process occurs at radius $r_0$ (equation 6), comparable to $r_{\text{min}}$. The star is strongly deformed by the tidal forces near $r_0$, but it barely touches its Roche lobe for a small fraction of the orbital period. As a result, the star loses a small amount of mass through the $L_1$ point at each pericentre passage. To our knowledge, this regime of tidal stripping was not explored by direct hydrodynamical simulations. Our crude estimates suggest two phases of stripping: the first phase lasts $N_1 \sim 10^3$ orbits until the star loses $\sim 1$ per cent of its mass. Then the mass-loss accelerates: the decrease in $M$ (and the corresponding increase in the WD radius) implies that the star overfills the Roche lobe more and more with every pericentre passage. As a result, the star loses the remaining 99 per cent of its mass in a few hundreds of additional orbits. The mass lost in each individual episode during these last hundreds of orbits behaves as $\delta M \propto (N_* - N)^{-4}$, where $N_* - N \ll N_*$ is the number of orbits remaining to complete disruption and $\xi \sim \psi/(\psi - 1)$.

According to our estimates, tidal stripping operates for days or weeks, creating a relatively long-lived source of gas. The gas can accrete on to the black hole and produce significant electromagnetic radiation together with the gravitational waves observed by LISA. The radiation source may become bright before the mass-loss spoils the standard EMRI template for the gravitational wave signal.

The gas produced by tidal stripping moves on nearly Keplerian orbits that are initially close to the WD orbit. The gas probably leaves the star with relative velocity $v_{\text{esc}} = (2GM/R)^{1/2}$ and its orbital energy differs from that of the star by a small fraction $v_{\text{esc}}/v \sim (M_0 M_{BH} R)^{1/2} \sim y^{-1/2}(M/M_{BH})^{1/3} \sim 1/30$. After $\sim 30$ orbital periods, the differential rotation of the gas has stretched it into a ring around the black hole. A non-zero eccentricity of the
donor orbit will create an eccentric ring. It should viscously spread and accrete on to the black hole. A small mass-loss fraction $x$ can be a huge source of gas for accretion. If most of the stripped matter is accreted by the black hole, the accretion rate is $\dot{M} \sim \delta M/P$. It exceeds the Eddington value $M_{\text{Edd}} \sim 10^{33} (M_{\text{BH}}/10^5 M_\odot) \text{ g s}^{-1}$ after $N \sim 10$ orbits since the beginning of tidal stripping, well before the final disruption of the WD. The accretion time-scale in the viscous ring can be estimated as $t_{\text{acc}} \sim \alpha^{-3} (H/r)^{-2} P$ where $P$ is the WD orbital period, $\alpha = 0.01$–0.1 is the viscosity parameter and $H$ is the thickness of the ring (e.g. Shakura & Sunyaev 1973). $H/r \sim 1$ is expected for super-Eddington accretion, which leads to $t_{\text{acc}} \sim (10–100) P$.

This suggests that a bright source with Eddington luminosity $L_{\text{Edd}} \sim 10^{41} \text{ erg s}^{-1}$ is created quickly, in less than 1 d after the beginning of tidal stripping. For a typical distance to such LISA sources, $d \sim 100$ Mpc, the accretion ring should be detectable with optical and X-ray telescopes provided its approximate location on the sky is known. LISA is expected to localize EMRIs within $\sim 10 \text{ deg}^2$ (Cutler 1998; Barack & Cutler 2004). For massive black hole mergers, the localization information will be available weeks to months prior to the final coalescence (Kocsis et al. 2007; Kocsis, Haiman & Menou 2008; Lang & Hughes 2008), and the localization expectations for WD EMRIs are similar (Drasco et al., private communications), giving sufficient time for simultaneous optical and X-ray observations during inspiral.

Mass transfer in WD inspirals is special as it creates a long-lived source of gas very close to the black hole horizon, $r_0 - r_g \sim r_g$. As a result, the donor orbit is generally not confined to a plane, if the black hole rotation is significant. Besides, the orbit will experience fast precession. Therefore, the freshly stripped gas may collide with the previously released gas and generate shocks (e.g. Evans & Kochanek 1989). The resulting pattern of accretion may be complicated and needs careful study.

An intriguing feature of tidal stripping is the periodic supply of gas to the WD. It may leave a fingerprint on the observed luminosity, modulating it with the WD orbital period $P$. The modulation of $\dot{M}$ may create a detectable oscillation in the luminosity from the accreting ring, even though the accretion time-scale $t_{\text{acc}} \sim (10–100) P$ tends to reduce the amplitude of modulation. The shock emission from collisions between the periodic flow from the WD and the gas accumulated around the black hole may be strongly modulated.

The description of mass transfer in this Letter is greatly simplified. The possibility of many repeated mass-transfer episodes is robust, but the exact rate of tidal stripping and the dynamics of accretion need to be explored with dedicated numerical simulations. The great potential that such events hold for joint detections of gravitational and electromagnetic radiation provides motivation for the effort. The joint detection would let us witness, in real time and unprecedented detail, the slow tidal stripping of a WD followed by its complete disruption. Note that LISA observations are expected to provide the mass and spin of the black hole, as well as the details of the inspiral orbit. This can be used to model in detail the hydrodynamics of accretion.

The scenario discussed in this Letter assumes $r_0 > r_{\text{min}}$ and uses a semi-Newtonian description for the WD orbit. A fully relativistic model will be needed to accurately evaluate the parameter space for such events. The relativistic effects are especially important if the black hole is rapidly rotating – then $r_0$ and $r_{\text{min}}$ will depend on the black hole mass $M_{\text{BH}}$, its spin parameter $a_s$, the eccentricity of the orbit and the angle between the orbital angular momentum and the angular momentum of the black hole. The competition between tidal disruption and gravitational capture by rotating black holes was investigated for parabolic orbits in Beloborodov et al. (1992). In a broad range of $M_{\text{BH}}$, the fate of a star approaching the black hole depends on the orbit orientation and can be either disruption or capture. For inspirals with $r_0 < r_{\text{min}}$, tidal stripping does not occur. Instead, $r_0$ reaches $r_{\text{min}}$ and the orbit loses stability before any mass is lost by the WD. Then the star is crushed by tidal forces as it falls into the black hole. This strong and immediate disruption is different from the gentle stripping considered here, suggesting rich phenomenology of WD inspirals.
