Abstract. Background/Aim: Both bariatric and thyroid surgeries promote calcium and vitamin D deficiency. The correlation, however, of hypocalcemia after thyroidectomy in patients with previous bariatric surgery has been poorly described. This review aimed to investigate the relationship between history of bariatric operations and post-thyroidectomy hypocalcemia, as well as suggested management options. Materials and Methods: MEDLINE and Cochrane databases were searched for relevant publications regarding post-thyroidectomy hypocalcemia in patients with previous bariatric surgery. Results: A total of 17 publications reporting on 126 patients met the inclusion criteria. These included 13 publications about Roux-en-Y gastric bypass (RYGB), 2 regarding biliopancreatic diversion (BPD), 1 about sleeve gastrectomy (SG) and 1 compared three bariatric procedures: SG, RYGB, laparoscopic adjustable gastric band (LAGB).

Post-thyroidectomy hypocalcemia was found to be more prevalent in patients with previous RYGB and BPD, but not in previous LAGB and SG. Conclusion: Patients with previous bariatric surgery are at high risk of post-thyroidectomy hypocalcemia that sometimes leads to higher length of hospital stay and demands more invasive solutions. There is a need, however, for additional studies and further investigation in order to reach more conclusive results.

Obesity has become a common health problem in western countries (1) and bariatric surgery is one of the most effective therapies for these patients. This procedure reduces the metabolic risk factors in morbidly obese patients and directly results in adequate weight loss. The most popular bariatric surgeries are Roux-en-Y gastric bypass (RYGB), sleeve gastrectomy (SG), biliopancreatic diversion (BPD) and laparoscopic adjustable gastric band (LAGB) (2, 3). Sleeve gastrectomy and the adjustable gastric band are restrictive procedures while the other two are malabsorptive ones.

Although very advantageous, bariatric surgery causes vitamin and mineral deficiencies, including that of calcium and vitamin D, leading to hypocalcemia (4). On the other hand, hypocalcemia is a common complication of thyroid surgery (5). Thus, as the number of post-gastric bypass patients increases, it is expected that an increased number of patients will be diagnosed with thyroid pathology requiring thyroid surgery. This combination of a
post-gastric bypass patient undergoing thyroidectomy is observed to potentiate the post-operative hypocalcemia.

However, despite the growing number of bariatric procedures, there are no established management guidelines for bariatric patients after thyroidectomy. Therefore, the present review aims to investigate the relationship between previous bariatric surgery and hypocalcemia after thyroidectomy.

Materials and Methods

MedLine and Cochrane databases were searched for “bariatric surgery”, “thyroid surgery”, “calcium”, “hypocalcemia”, “low calcium” combined with the boolean operators AND/OR. The abstract list generated by the search was screened by two authors (ES and DIA). The search was limited to papers describing original patient data written in English, case reports and case-control and matched paired analyses. The final search was performed on January 27th, 2019. The results of the search and the selection process are summarized in a flow-chart (Figure 1). Out of 35 results and application of the snowball procedure, 17 publications were found to meet the criteria set and were, therefore, analyzed (Table I).

Results

Manco et al. (2004) (6) have studied 4 cases of women who had undergone a near-total thyroidectomy for multinodular goiter following a BPD procedure. In the post-operative period, patients suffered from lipid malabsorption and three of them developed symptomatic hypocalcemia treated with oral and IV administration of calcium and vitamin D. The fourth patient received IV calcium gluconate, as a preventive treatment, immediately following the procedure and for the next three days. That led to her to safe discharge without any hypocalcemia symptoms. On the other hand, one of the rest, developed severe, resistant hypocalcemia not responding to oral or IV treatment. Thus, she underwent a reoperation in order to elongate the common limb of BPD.

Rojas-Marcos et al. (2005) (7) have reported a case of a young woman who underwent BPD and three years later she was diagnosed with a suspicious thyroid nodule. Total thyroidectomy with central neck lymphadenectomy was performed without any complications, preserving at least 3 parathyroid glands. One week later, she experienced hypocalcemia related symptoms that were resistant to standard pharmaceutical supplementation. However, hypocalcemia subsided when the calcium and vitamin D doses were increased.

In a study by Piertas et al. (2008) (8), there was a case reported about a middle-aged woman with a recent history of RYGB, who had a near total thyroidectomy for a Hurthle cell adenoma. Post-operatively, she had symptoms of hypocalcemia requiring her to remain in the hospital for a week in order to receive both oral and IV calcium along with Vitamin D. Finally, a year after the discharge, the hypocalcemia persisted, and she was required to receive oral vitamin D and calcium supplementation for life.

Similar results have been reported by Salinger et al. (2010) (9) regarding patient who underwent near total thyroidectomy for multi-nodular goiter 5 years after a RYGB. It was stated that the 40-year-old woman had normal pre and postoperatively values of calcium and vitamin D but at postoperative day 2 she presented with paresthesia and perioral numbness. Calcium was below normal, and she stayed 8 days in the hospital to receive IV calcium gluconate and vitamin D along with oral regiments to fully recover.

Panazzolo et al. (2014) (10) have presented a case of a young woman who underwent an RYGB surgery for morbid obesity. Her past surgical history included a previous right thyroid lobectomy for a benign nodule. Following bariatric surgery, she was diagnosed with a new thyroid nodule necessitating a complete thyroidectomy. In the first postoperative day, she depicted symptoms of hypocalcemia and required IV calcium, even though prior to the surgery all of her laboratory test results were normal, including that of thyroid’s, vitamin D and calcium. The patient had difficulties to manage hypoparathyroidism as shown by the multiple admissions in the emergency department for hypocalcemia. As an adjuvant to the oral and IV supplementation of calcium and vitamin D, she was prescribed pancreatic lipase, which led to the normalization of both calcium, phosphorus and vitamin D levels.

An interesting case has been described by Vemuri et al. (2015) (11). A 45-year-old female with a history GS underwent a near-total thyroidectomy for a follicular neoplasm of the left thyroid lobe. In the postoperative period, even though vitamin D was normal and calcium and PTH

were in the low ends of the normal range, the patient developed symptoms of hypocalcemia requiring calcium carbonate and calcitriol. However, the symptoms persisted despite IV administration of calcium gluconate. Subsequent treatment with calcium acetate led to her discharge.

In 2016, Baldane et al. (2016) (12) similarly to Palazzolo’s case, reported a case of a young female patient with resistant hypocalcemia one year after total thyroidectomy for a benign nodule. The patient had a previous history of an RYGB surgery. Despite high doses of calcium, calcitriol, ergocalciferol, and magnesium, she needed the addition of pancreatic lipase to achieve satisfying levels of calcium.

The two patients, discussed by Campos et al. (2014) (13), underwent RYGB reversal after encountering severe postoperative hypocalcemia following a thyroidectomy procedure. They were initially treated with calcium tablets, vitamin D and recombinant parathyroid hormone (rPTH) without any result. After the failure of IV administration of calcium, a gastrostomy (G-tube) was placed in order to deliver calcium and other nutrients through the excluded stomach and the duodenum. That initiative led to an
improvement of the hypocalcemia confirming that an RYGB reversal would alleviate the symptoms.

McKenzie et al. (2013) (14), have evaluated 19 patients with previous RYGB who underwent thyroidectomy. After performing a case-matched study with 38 controls, they discovered that the 19 patients had a greater chance of acquiring symptomatic hypocalcemia (42% vs. 0%, \( p<0.01 \)), requiring IV calcium requirement (21% vs. 0%, \( p<0.01 \)) and as a consequence, prolonged hospital stay (2.2 vs. 1.2 days, \( p=0.02 \)).

The study by Dequanter et al. (2016) (15) has included 14 patients with previous RYGB history who underwent total thyroidectomy. These patients were case-matched with 23 controls. It was revealed that patients with a history of RYGB were more prone to develop symptomatic hypocalcemia compared to controls (38% vs. 0%, \( p<0.01 \)). Moreover, the duration of hospital stay was higher (2.2 vs. 1.2 days, \( p=0.02 \)). In this study, all patients developing recalcitrant hypocalcemia with a serum calcium of less than 6.5 mg/dl were treated with IV administration of calcium as adjunctive to the oral supplementation. As such, 18% of the RYGB group received IV administration of calcium compared to 0% of the control group, \( p<0.01 \).

Gross et al. (2014) (16) have reported a middle-aged man with a history of previous RYGB, who had undergone total thyroidectomy with central and bilateral neck dissection due to metastatic papillary carcinoma. After surgery, he had severe hypocalcemia and required aggressive oral and IV repletion therapy with calcium, magnesium, vitamin D and a thiazide diuretic, thus, normalizing the levels of calcium and PTH.

In a 2015, Alfonso et al. (17) reported on a case of a 58 years old woman who had undergone total thyroidectomy for the follicular variant of papillary thyroid carcinoma. Her history included RYGB surgery. Postoperatively, she developed severe symptomatic hypocalcemia that required large doses of calcium and vitamin D via IV and the oral route. In spite of her persistent hypoparathyroidism, she acquired a normal level of calcium.

The study by Durr et al. (2009) (18) included 2 patients with postoperative hypocalcemia after total thyroidectomy and a history of RYGB surgery. They required 12 and 16 days of IV administration of calcium, respectively.

Allo Miguel et al. (19) have reported the use of teriparatide in their patient who underwent thyroid surgery after a bariatric procedure but the response was not satisfactory and they reversed RYGB.

A different approach was followed by Gooi et al. (2014) (20) in order to address the postoperative hypocalcemia that obese patients, with such surgical history, so often develop. The three patients included in this study underwent a staged total thyroidectomy with 2-3 months interval between the two operations. The first and third patient were diagnosed with a papillary thyroid microcarcinoma (PMTC) while the second one with papillary thyroid carcinoma (PTC). The staged procedure included two operations, initially a lobectomy and isthmectomy at the side of the PTC or PMTC followed by completion thyroidectomy three months later. At the end of the staged procedure all patients were normocalcemic, evading the not so rare side effects of hypocalcemia that are commonly observed in these patients.

A unique study, published by Chereau et al. in 2016 (21), presented patients who were operated for thyroid pathology and had undergone different types of bariatric surgery, including RYGB, SG, and LAGB. These patients were matched with patients without a history of bariatric operation. Eventually, 48 patients were reported, 19 of whom had postoperative hypocalcemia which persisted in only 5 of them. The only risk factor that was linked with hypocalcemia was found to be the type of surgery. Specifically, in RYGB procedures the risk of hypocalcemia was double than that in SG or LAGB (60% vs. 30%). Furthermore, in a match-paired analysis, the risk of reduced levels of calcium was found to be increased in patients with previous bariatric surgery and history of thyroidectomy compared with those who did not have any thyroid surgery (40% vs. 15%). Likewise, the mean length of hospital stay was increased in the latter category (4.2 vs. 1.9 days, \( p<0.001 \)).

In contrast to the previous studies, Droeser et al. (22) have reported different results. They created a cohort study by identifying patients from the Scandinavian Quality Registry for Thyroid, Parathyroid and Adrenal Surgery (SQ RTPA) and from the Swedish Obesity Surgery (SOReg). They included patients with previous obesity surgery and a subsequent total thyroidectomy over the period of 2004 to 2015. Out of 6115 patients with total thyroidectomy, only 25 met the inclusion criteria. There was no statistically significant difference in postoperative total calcium levels between patients with or without previous RYGB following total thyroidectomy. This large population-based analysis did not confirm that the patients with previous RYGB are at higher risk of post-thyroidectomy hypocalcemia.

**Discussion**

It is known that bariatric operations cause nutritional deficiencies and thus patients require postoperative supplementation. The most common deficiencies concern that of iron, proteins, vitamin B12, calcium, magnesium, Vitamin D and other fat-soluble vitamins (23). This is mainly the result of bypassing critical portions of the gastrointestinal tract that absorb these nutrients, along with the reduced stomach acidity as a result of these operations (24-26). Specifically, regarding calcium, the main site of absorption is in the duodenum and proximal jejunum. In a healthy adult individual, 80-100% of dietary calcium is absorbed by the duodenum via a vitamin D dependent transcellular active transport mechanism (27). In the case that duodenum is bypassed, calcium is absorbed by a weaker paracellular
hypocalcemia following a thyroidectomy, in patients with doses of calcium citrate and calcitriol. Calcium citrate is previous bariatric surgery, it may be needed to prescribe high supplements to the patients postoperatively, which, postoperative hypocalcemia is the reduction of serum PTH minimized by prescribing calcium and/or vitamin D (28-30). Another reason is that the reduced uptake of daily calories after bariatric surgeries leads to a reduction of daily vitamin D to almost half (9). Also, most bariatric patients develop an intolerance to calcium-rich foods after surgery (31). As a consequence, obese patients are particularly susceptible to vitamin D and calcium deficiency (1-3, 18, 32-35). In addition, depending on the type of bariatric operation there are different consequences on the vitamin D levels. As observed from other studies, RYGB and BPD operations, due to their nature, further decrease the intestinal absorption of vitamin D (2, 3, 36) and that of calcium (21). However, there seems to be no difference in the absorption of any other nutrient between RYGB and other bariatric operations such as GS (37).

Apart from the bariatric operations, thyroidectomy is another common procedure that may cause hypocalcemia (38, 39). Specifically, it is the most common complication of total thyroidectomy, concerning 20% of the patients (5), with 10% of them being symptomatic (40), while permanent hypoparathyroidism is associated with hypocalcemia in about 1-3% (38). There are many known risk factors for post-thyroidectomy hypocalcemia such as inadvertent excision of parathyroid glands, low preoperative vitamin D level, bilateral central lymph node neck dissection, thyroid diseases such as autoimmune Hashimoto thyroiditis and female gender (38, 39).

The main pathophysiology of the resulting transient hypocalcemia is the parathyroids’ malfunction due to the stress inflicted by the surgical handling during the operation. On the other hand, permanent hypocalcemia most commonly occurs following a thyroid operation when the parathyroid glands are accidentally excised. The transient hypocalcemia can be minimized by prescribing calcium and/or vitamin D supplements to the patients postoperatively, which, unfortunately, does not decrease the risk of permanent hypoparathyroidism (41). However, the only confirmed way of predicting postoperative hypocalcemia is the reduction of serum PTH concentration occurring 4-8 hours after the procedure (42, 43).

In addition, even though hypocalcemia following thyroidectomy is a very common complication, its prevalence gets even higher in patients with previous bariatric surgery (14, 21).

In order to control refractory and symptomatic hypocalcemia following a thyroidectomy, in patients with previous bariatric surgery, it may be needed to prescribe high doses of calcium citrate and calcitriol. Calcium citrate is argued to have better absorption than calcium carbonate due to the existing low gastric acid in the stomach (27) and low calcitriol in bariatric patients. Upgrading treatment options should only be considered after giving the highest oral dose of calcium and vitamin D, because the hypocalcemia seen in these patients often completely resolves by increasing the dose (7, 21). Low levels of magnesium also need to be restored because when severely depleted, they can reduce the PTH secretion (8, 16). In refractory cases, the second step is establishing an IV route of calcium administration and vitamin D supplementation which has very promising results (6, 8, 9, 11, 14-18) with the exception of the study by Pietras et al., which showed that the patients required permanent calcium administration at home (8). In case of failure, switching from IV administration of calcium gluconate to calcium acetate may resolve the issue (11). The next step for refractory hypocalcemia is teriparatide, a recombinant PTH, which can be used as an alternative to vitamin D non-responsive hypoparathyroidism (39, 44). However, the results are not very specific, especially in patients with previous bariatric surgery, thus additional studies should be conducted to identify teriparatide’s effectiveness in refractory hypocalcemia (44, 45). If the hypocalcemia is resistant, the addition of a thiazide diuretic such as hydrochlorothiazide may be effective due to its favorable action on calcium absorption in the distal tubule of the kidneys (35). An alternative treatment, which is specific to the hypocalcemia of those patients, is the administration of pancreatic lipase in combination with high doses of calcium, magnesium and vitamin D (10, 12, 44).

When medication therapy fails, the recalcitrant hypocalcemia can be managed with more invasive methods. As shown in one of the patients of Manco et al. (6), a sufficient treatment is the elongation of the common limb of BPD, increasing the time that nutrients are mixed with the biliopancreatic secretions leading to improved absorption.

Finally, the last resort is the reversal of the bariatric procedure. As Campos et al. have depicted in their publication (12), the initial step entails confirmation that hypocalcemia subsides upon feeding the patient through a G-tube, going through the previously excluded portion of the stomach. If it resolves, there is a higher chance the reversal to the previous anatomy to resolve the hypocalcemia. The same approach was applied by Allo Miguel et al. (19) with similar promising results. However, the most impactful solution for patients who undergo thyroidectomy with a previous bariatric surgery is to avoid this complication from the beginning. As has been shown by Gooi et al. (20), performing a staged thyroidectomy on very high-risk patients can help avoid the almost unavoidable recalcitrant hypocalcemia. Moreover, another preventive measure is to replete calcium via IV administration of calcium gluconate as seen at one of the patients of Manco et al. (6), avoiding postoperative hypocalcemia.
Conclusion

Bariatric surgery is an independent risk factor for post-thyroidectomy hypocalcemia. This adverse event is more commonly seen in RYGB and BPD. Initially, the reduced calcium can increase the length of stay at the hospital and require patients more invasive treatment options. In more severe cases, it can lead to permanent hypocalcemia with concomitant secondary hyperparathyroidism further increasing the morbidity of these patients. Thus, ways to decrease the hypocalcemia risk, such as treatment with calcium and vitamin D prior to the procedure or performing a staged thyroidectomy seems to have promising results. However, additional studies are needed to further confirm this argument.
