The anisotropy splitting in the ground state of the single-molecule magnet \([\text{[Mn}_4\text{O}_3\text{Br(OAc)}_3\text{dbm)}_3]\) is studied by inelastic neutron scattering as a function of hydrostatic pressure. This allows a tuning of the anisotropy and thus the energy barrier for slow magnetisation relaxation at low temperatures. The value of the negative axial anisotropy parameter \(D_{\text{cluster}}\) changes from -0.0627(1) meV at ambient to -0.0603(3) meV at 12 kbar pressure, and in the same pressure range the height of the energy barrier between up and down spins is reduced from 1.260(5) meV to 1.213(9) meV. Since the Mn – Br bond is significantly softer and thus more compressible than the Mn – O bonds, pressure induces a tilt of the single ion Mn\(^{3+}\) anisotropy axes, resulting in the net reduction of the axial cluster anisotropy.

---

Single-molecule magnets (SMM) are presently the focus of a very intense research activity. SMM are molecules containing a finite number of exchange coupled magnetic ions, and they exhibit phenomena such as slow relaxation and quantum tunneling of the magnetisation at low temperatures \(^1\). They are the smallest known units that are potentially capable of storing a bit of information at cryogenic temperatures. An easy axis type magnetic anisotropy is an essential prerequisite for an energy barrier between up and down spins and thus for slow relaxation. The height of this barrier is determined by both the ground state \(S\) value and the size of the negative \(D\) value in the axial spin Hamiltonian

\[
\hat{H}_{\text{axial}} = D \left[ S_z^2 - \frac{1}{3} S (S + 1) \right]
\]

For even and odd \(S\) values the barrier height is given by \(|D|S^2\) and \(|D|(S^2 - \frac{1}{3})\), respectively. Chemists have been able to assemble numerous spin clusters which show SMM features at the very lowest temperatures. But the number of examples with blocking temperatures above 1 K is still rather limited. Among them is a family of tetranuclear manganese clusters with general formula \([\text{Mn}_4\text{O}_3\text{X(OAc)}_3\text{dbm)}_3]\), where OAc\(^-\) is the acetate ion and dbm\(^-\) is the anion of dibenzoylmethane. They all exhibit SMM behavior with an energy barrier of the order of 1.25 meV \(^2\). Here we report the first direct spectroscopic determination of the anisotropy splitting in a SMM under hydrostatic pressure. The molecule \([\text{Mn}_4\text{O}_3\text{Br(OAc)}_3\text{dbm)}_3]\) (Mn\(_4\)) belongs to the above family, and its molecular structure is shown in Figure 1a.

---

FIG. 1: a) Molecular structure of the title complex Mn\(_4\), from Ref. \(^3\). View along the approximate C\(_3\) axis. For clarity the H atoms are omitted. Mn\(^{3+}\) ions are drawn as large black spheres, C and O atoms as small black and grey spheres, respectively. The large grey sphere represents the Br\(^-\) ion, which obscures the Mn\(^{4+}\) ion just behind. b) Schematic view of the core of Mn\(_4\), with III and IV representing Mn\(^{3+}\) and Mn\(^{4+}\), respectively. The black and grey positions of the Br\(^-\) ion schematically represent the situation at ambient and high external pressure, respectively.

The molecule has a \([\text{Mn}^{4+}(\text{Mn}^{3+})_3(\mu_3 - \text{O})_3(\mu_3 - \text{Br})]^{6+}\) core with a distorted cubane geometry, which is schematically depicted in Figure 1b. The molecular point symmetry is approximately C\(_{3v}\) with the C\(_3\) axis passing through the Mn\(^{3+}\) and Br\(^-\) ions (Figure 1b). \(^4\). We correlate the pressure dependence of the anisotropy splitting with pressure induced changes in the structure and identify the dominant terms and factors which govern the anisotropy splitting and thus the barrier height.

Inelastic neutron scattering (INS) is the most direct
technique to measure anisotropy splittings in SMMs in the absence of an external magnetic field. Among others, anisotropy parameters have thus been obtained for the prototype SMMs Mn$_{12}$-acetate [4] and [Fe$_8$O$_2$(OH)$_{12}$(tacn)$_6$]$^{8+}$ [5] as well as four members of the Mn$_4$ cubane family including the title compound [2].

The present measurements were carried out on a partially deuterated sample with composition [Mn$_4$O$_3$Br(d$_{3}$-OAc)$_3$(dbm)$_3$] using the time-of-flight spectrometer IN5 at the Institut Laue Langevin (ILL) in Grenoble. The sample was prepared according to Ref. [6]. For pressures of 0 kbar, 3 kbar and 5 kbar about 2 grams of polycrystalline sample placed in a standard ILL continuously loaded high-pressure cell with He as the pressure transmitting medium were used. For 12 kbar the standard ILL high-pressure clamped cell was employed with about 0.3 grams of sample. Neutron wavelengths of 7.5 Å (0 kbar to 12 kbar) and 8.5 Å (0 kbar to 5 kbar) were used, corresponding to instrumental resolutions of 32 µeV and 19 µeV, respectively. The data treatment involved the calibration of the detectors by means of a spectrum of vanadium metal.

Experimental results for 0 kbar, 5 kbar and 12 kbar at 18 K are shown in Figure 2a. At this temperature all the ground state levels have some population. At all pressures four well resolved inelastic peaks, labelled I to IV, are observed on both the energy loss and gain side, corresponding to positive and negative energy transfers in Figure 2a, respectively. The 12 kbar peaks are slightly inhomogeneously broadened. At 2 K only peak I is observed, and this is shown on an expanded energy scale in Figure 2b. A decrease of the peak energy with pressure is evident. An analysis using Gaussian fits to the background corrected data yields the peak positions in Table I. The data at ambient pressure are in good agreement with those reported in Ref. [2].

Antiferromagnetic exchange interactions between the three Mn$^{3+}$ ($S = 2$) ions and the Mn$^{4+}$ ($S = \frac{3}{2}$) ion dominate the coupling in Mn$_4$, thus leading to a $S = \frac{3}{2}$ cluster ground state, with the first excited $S = \frac{5}{2}$ state at about 22 meV and thus outside the range of our experiment. The trigonal symmetry of the Mn$_4$ molecules in the crystal structure of the title compound is slightly distorted, as can be seen in Figure 1a, with an actual point group symmetry C$_1$. Including a higher order term the appropriate spin Hamiltonian to account for the splitting of the $S = \frac{3}{2}$ ground state is thus given by

$$\hat{H}_{\text{aniso}} = D \left[ \hat{S}_z^2 - \frac{1}{3}S(S+1) \right] + B_4 \hat{O}_4 + E \left( \hat{S}_x^2 - \hat{S}_y^2 \right)$$

where $\hat{O}_4 = 35\hat{S}_z^4 - [30S(S+1) - 25] \hat{S}_z^2 - 6S(S+1) + 3S^2(S+1)2$.

From the data in Ref. [2] the following parameter values at 18 K were determined: $D = -0.062$ meV, $B_4^4 = -6.3 \times 10^{-6}$ meV and $E = 2.1 \times 10^{-3}$ meV. The first term in Eq. 2 is the leading term, and thus $M_S$ remains a reasonably good quantum number. The splitting pattern with the above parameters is shown in Figure 3.
Magnetic neutron scattering theory leads to the selection rules $\Delta M_S = 0, \pm 1$ for INS, i.e. transitions between adjacent levels are allowed, see the arrows in Figure 2. We can thus immediately assign the observed INS bands I to IV in Figure 2, as given in the second column of Table I. Fitting the eigenvalues of Eq. 2 to the observed band energies yields the parameter values at the bottom of Table I. Both $|B^4_0|$ and $|E|$ are much smaller than $|D|$, but they are essential for a proper description, and they are responsible for the deviations from a regular spacing of the peaks in Figure 2. The parameter values at ambient pressure are the same within experimental accuracy as those derived from the data in Ref. 2. The negative $D$ is significantly pressure dependent, its value decreasing linearly by 3.8% between ambient pressure and 12 kbar. This leads to a reduction of the energy barrier, i.e. the energy difference between the $M_S = \pm \frac{1}{2}$ and $M_S = \pm \frac{3}{2}$ levels, from 1.260(5) meV at ambient to 1.213(9) meV at 12 kbar pressure, respectively. The pressure dependence of $B^4_0$ and $E$ is too small to be determined by our experiment.

The only pressure experiments on single-molecule magnets reported in the literature are for Mn$_{12}$-acetate. From the pressure dependence of the low temperature magnetisation it was concluded that pressure produces a geometrical molecular isomer of Mn$_{12}$-acetate with significantly faster relaxation of the magnetisation 7. On the other hand, changes in the position of the steps in the hysteresis of Mn$_{12}$-acetate under pressure were ascribed to an increase of the axial anisotropy splitting with pressure 8. Our experimental finding for Mn$_4$ that the axial anisotropy splitting is decreasing with pressure is unambiguous. With the following simplified model we account for this decrease by correlating it with the expected structural changes of the molecule under pressure. We assume an isotropic compressibility for the core defined by the three Mn$^{3+}$ ions and the Mn$^{4+}$ ion in Figure 4. All the metal-ligand bonds in this core are either Mn$^{3+}$–O or Mn$^{4+}$–O bonds, and taking average linear compressibilities ($d$) from the literature we calculate $d(12$ kbar$)/d(ambient) = 0.9975$ 8. The Mn$^{3+}$–Br bonds in Figure 4 are significantly softer and more compressible than the Mn–O bonds. A ratio of force constants $k$(Mn$^{3+}$–O)/$k$(Mn$^{3+}$–Br) = 4.2 is obtained from literature values based on Raman experiments 10, 11. In terms of compressibility we thus calculate a ratio $d(12$ kbar$)/d(ambient) = 0.993$ for the Mn$^{3+}$–Br$^-$ bonds. The net effect of pressure in this simplified model is an increase of the apex angle at the Br position of the molecule. Between ambient and 12 kbar pressure this angle $\alpha$, defined in Figure 4b, increases from 42.5° to 42.75°. Since the Jahn-Teller axis of the Mn$^{3+}$ coordination is close to the Mn–Br direction, pressure induces an inward tilt of the three Mn$^{3+}$ anisotropy axes, thus decreasing the cluster anisotropy. The value of the axial anisotropy parameter of the cluster in the $S = \frac{3}{2}$ ground state can be expressed as 12:

$$D_{\text{cluster}} = \frac{105}{484}D_{\text{Mn}^{3+}}(3\cos^2 \alpha - 1) + \frac{35}{121}D_{33} - \frac{7}{44}D_{34}$$

(3)

where $D_{\text{Mn}^{3+}}$ is the single ion $D$ parameter of the Mn$^{3+}$, $D_{33}$ and $D_{34}$ are magnetic dipole-dipole interaction terms between Mn$^{3+}$–Mn$^{3+}$ and Mn$^{3+}$–Mn$^{4+}$, respectively. These latter two terms in Eq. 3 can be calculated 12, they are typically an order of magnitude smaller than the experimental $D$, and their sum is practically pressure independent, see Table II. We can thus definitely rule out that the observed reduction of $|D_{\text{cluster}}|$ with pressure is due to a change in the dipole-dipole interaction. On the other hand, the $(3\cos^2 \alpha - 1)$ factor in the first term of Eq. 3 has a significant effect. With the estimated increase of $\alpha$ by 0.25° at 12 kbar and taking $D_{\text{Mn}^{3+}}$ as pressure independent we calculate a 2.1% reduction of the $|D_{\text{cluster}}|$ value at 12 kbar. This is to be compared with the reduction of 3.8% derived experimentally. We note that for $\alpha = 42.5°$ in Mn$_4$ the function $(3\cos^2 \alpha - 1)$ is highly susceptible to minute changes of $\alpha$. Since our compressibility model is rather crude, the estimated pressure dependence of $\alpha$ has a relatively large uncertainty, which is amplified for the factor $(3\cos^2 \alpha - 1)$. We therefore feel confident that we have identified the principal structural element in Mn$_4$, which leads to a decrease of the axial anisotropy under hydrostatic pressure. The compression of the apex with the resulting increase of $\alpha$ is schematically represented in Figure 4b, by the grey Br position.

Chemical variation is another way of tuning the cluster...
TABLE II: Experimental INS peak positions and calculated transition energies using Eq. 2 as a function of hydrostatic pressure. The labeling corresponds to Figure 2 and the assignments in the second column refer to Figure 3. Parameter values for each are given at the bottom. The pressure dependence of $|E|$ and $D^2_\parallel$ is too small to be determined in this experiment, and the values determined at ambient pressure were used throughout.

| label transition | $p = 0$ kbar | $p = 3$ kbar | $p = 5$ kbar | $p = 12$ kbar |
|------------------|--------------|--------------|--------------|--------------|
| X = Cl, ambient | $D_{\text{cluster}}$ (meV) | $D_{\text{sd}}$ (meV) | $D_{\text{Mn}^{3+}}$ (meV) | $\alpha$ ($^\circ$) | $3 \cos^2 \alpha - 1$ |

$^b)$calculated using Ref. [12]

$^c)$from Ref. [3]

$^d)$assumed to be pressure independent

$\alpha$ calculated as described in the text

TABLE II: $D_{\text{cluster}}$ values of $[\text{Mn}_2\text{O}_4\text{X}((\text{OAc})_2)_2(\text{dbm})_3]$ ($X = \text{Cl, Br})$ determined by INS. $D_{\text{sd}}$ is the calculated sum of the two dipole-dipole contributions $D_{\text{sd}}$ and $D_{\text{sd}}$ in Eq. 3. $D_{\text{Mn}^{3+}}$ is the single-ion $D$ parameter calculated from $D_{\text{cluster}}$ using Eq. 3. $\alpha$ is the angle at the apex of the cluster defined in Figure 1b, and $(3 \cos^2 \alpha - 1)$ is the factor in the first term of Eq. 3.

In conclusion, we have presented the first direct determination of the pressure dependence of the axial anisotropy splitting in a SMM. Hydrostatic pressure of 12 kbar reduces the energy barrier between plus and minus spins by 3.8%. The reduction mainly results from a tilting of the single ion anisotropy axes of Mn$^{3+}$ under pressure. Very recent INS experiments on Mn$_{12}$-acetate show a very small increase of $|D|$ with increasing hydrostatic pressure. This different behavior confirms our conclusion that the pressure dependence is a property determined by the specific structure of a SMM molecule.
