The self-consistent cranking method is tested by comparing the cranking calculations in the interacting boson model with the exact results obtained from the SU(3) and O(6) dynamical symmetries and from numerical diagonalization. The method is used to study the spin dependence of shape variables in the $sd$ and $sdg$ boson models. When realistic sets of parameters are used, both models lead to similar results: axial shape is retained with increasing cranking frequency while fluctuations in the shape variable $\gamma$ are slightly reduced.

I. INTRODUCTION

Self-consistent cranking (SCC) is one of the most popular methods to study collective rotations in nuclear many-body systems [1]. Within the Hartree-Fock framework, it has provided important insights into the backbending phenomena, and currently, it is being used actively in studies of superdeformed nuclei [2]. In stark contrast, it has been rarely used in the interacting boson model (IBM) [3]. In fact, there is only one application of SCC to IBM where a study of moment of inertia (MOI) is carried out [4]. In the early stages of the model, an obvious reason for this neglect was the availability of exact results (either via dynamical symmetries or numerical diagonalization), which left little room for development of approximate methods such as SCC. In later extensions of the IBM (e.g. $sdg$-IBM), dynamical symmetries were not very useful, and numerical diagonalization could not be carried out due to large basis space, hence alternative methods were needed. At around the same time, however, an exact angular momentum projection technique was developed for axially symmetric boson systems ($1/N$ expansion [5]), which provided analytical solutions for general Hamiltonians in large basis spaces, filling the gap left by the other methods. Although the assumption of axial symmetry is reasonable for most deformed nuclei in their ground states, triaxial effects are known to play a role, especially at high-spins [6]. Therefore a study of the evolution of shapes in the IBM would be useful in order to investigate such questions as the effects of triaxiality in nuclear spectra, ways of incorporating it in the IBM Hamiltonian, and whether an improved description of spectra can be obtained if triaxial effects are taken into account.

In this paper, we first present tests of the SCC by comparing the cranking calculations with the exact results obtained in the SU(3) and O(6) limits, as well as from diagonalization of more realistic Hamiltonians in the $sd$-IBM. The SCC method is then used in a study of triaxiality in the IBM both in the $sd$ and $sdg$-boson versions of the model.

II. CRANKING FORMALISM IN THE IBM

The SCC in the IBM was formulated in Ref. [4] to which we refer for details, especially concerning the construction of the intrinsic state and the symmetries it possesses. For a given IBM Hamiltonian $H$ and intrinsic state $|N, \mathbf{x}\rangle$, the SCC around the $x$-axis is described by

$$\delta \langle N, \mathbf{x} | H - \omega \hat{L}_x | N, \mathbf{x} \rangle = 0,$$

where $\hat{L}_x$ is the $x$-component of the angular momentum operator, $N$ is the boson number and $\mathbf{x}$ are the variational parameters to be determined from the extremum condition. For convenience, we consider a general formulation of the IBM which will be tailored to specific cases later. Thus, we introduce the boson creation and annihilation operators

*E-mail: sek105@rsphysse.anu.edu.au
$b^\dagger_{l\mu}, b_{l\mu}$ with $l = 0, 2, 4, \ldots$ where $b_0 = s$, $b_2 = d$, $b_4 = g$, etc. The intrinsic state is given by a condensate of intrinsic bosons as

$$|N, \mathbf{x}\rangle = (N!)^{-1/2}(b^\dagger)^N|0\rangle, \quad b^\dagger = \sum_l \sum_{m=-l}^l x_{lm} b^\dagger_{lm},$$

where $x_{lm}$ are the normalized boson mean fields, i.e. $\mathbf{x} \cdot \mathbf{x} = 1$. Due to the symmetries in the cranked system, $x_{lm}$ are real and $x_{l-m} = x_{lm}$. Note that the odd-$m$ components of $x_{lm}$ vanish in the static limit ($\omega = 0$), but not in general. Thus, invoking the normalization condition (e.g. setting $x_{00} = 1$), there are 3 independent variational parameters in the $sd$-IBM ($x_{20}, x_{21}, x_{22}$) and 5 more in the $sdg$-IBM ($x_{40}, \ldots, x_{44}$). For the IBM Hamiltonian, we use the generic multipole form

$$H = \sum_l \varepsilon_l \hat{n}_l - \sum_{k=0}^{2l_{\text{max}}} \kappa_k T^{(k)} \cdot T^{(k)},$$

where the boson number and multipole operators are given by

$$\hat{n}_l = \sum_{\mu} b^\dagger_{l\mu} b_{l\mu}, \quad T^{(k)} = \sum_{jl} t_{klj} [b^\dagger_{l\mu}]^{(k)}_{\mu}.$$  

In particular, the angular momentum operators are

$$\hat{L}_x = \frac{-1}{\sqrt{2}} (\hat{L}_+ - \hat{L}_-), \quad \hat{L}_\mu = \sum_l \sqrt{l(l+1)(2l+1)/3} \ [b^\dagger_{l\mu}]^{(1)}_{\mu}.$$  

The parameters of the Hamiltonian consists of the single boson energies, $\varepsilon_l$, the multipole coupling strengths, $\kappa_k$, and the multipole parameters, $t_{klj}$. The hermiticity condition on multipole operators requires that $t_{klj} = t_{lkj}$.

The expectation values in Eq. (3) can be evaluated in a straightforward manner using boson calculus techniques. For the one-body operators, one simply obtains

$$\langle N, \mathbf{x} | \hat{n}_l | N, \mathbf{x}\rangle = N \sum_m x^{2}_{lm} \mathbf{x} \cdot \mathbf{x}. \tag{6}$$

Calculations for the multipole interactions are somewhat more involved but the expectation values can again be reduced to a compact form

$$\langle N, \mathbf{x} | T^{(k)} \cdot T^{(k)} | N, \mathbf{x}\rangle = N(N-1) \sum_{\mu=-k}^{k} (-1)^{\mu} A_{k\mu} A_{k-\mu} + N \sum_l \varepsilon'_l \sum_m x^{2}_{lm} \mathbf{x} \cdot \mathbf{x}. \tag{7}$$

Here $A_{k\mu}$ corresponds to the expectation value of the operator $T^{(k)}_{\mu}$ in a single boson state and is given by

$$A_{k\mu} = \sum_{jnlm} (-1)^m (jnlm|k\mu) t_{klj} x_{ln} x_{lm} \mathbf{x} \cdot \mathbf{x}. \tag{8}$$

Using the symmetries imposed on the mean fields and the hermiticity condition, it can be shown that $A_{k\mu}$ vanishes if $k + \mu$ is odd, and furthermore $A_{k-\mu} = (-1)^k A_{k\mu}$. Thus, for even multipoles, only the positive, even $\mu$ values contribute to the sum in Eq. (8). The second term in Eq. (9) arises from the normal ordering of the boson operators and corresponds to an effective one-body term with boson energies

$$\varepsilon'_l = \frac{2k+1}{2l+1} \sum_j t^2_{kjl}. \tag{9}$$

Finally, the expectation value of $\hat{L}_x$ is

$$\langle N, \mathbf{x} | \hat{L}_x | N, \mathbf{x}\rangle = -N \sum_{lm} (-1)^m (lnl-m|11) \sqrt{2l(l+1)(2l+1)/3} \frac{x_{ln} x_{lm}}{\mathbf{x} \cdot \mathbf{x}}. \tag{10}$$
For a given angular frequency $\omega$, the cranking equation (11) is solved numerically by minimizing the cranking expression $E(x, \omega) = \langle H - \omega L_x \rangle$ with respect to the mean fields $x$. The dynamical MOI is calculated from the derivative of $\langle L_x \rangle$, Eq. (10) as

$$J^{(2)} = \frac{d\langle L_x \rangle}{d\omega},$$

(11)

which is obtained under the assumption $\langle L_x \rangle \simeq L$. For the exact energy levels $E(L)$, dynamical MOI and the corresponding rotational frequencies are calculated from

$$\omega = \frac{1}{4\hbar} [E(L + 2) - E(L - 2)].$$

(12)

Evolution of triaxiality with rotation is studied using the following expressions for the collective shape variable $\gamma$

$$\tan \gamma = \sqrt{2} \frac{\langle Q_2 \rangle}{\langle Q_0 \rangle},$$

(13)

$$\cos 3\gamma = -\sqrt{\frac{7}{2}} \frac{\langle Q \cdot Q \cdot Q \rangle}{\langle Q \cdot Q \rangle^{3/2}}.$$  

(14)

The one-body expectation values of the quadrupole operator in Eq. (13) follow from Eq. (8) as $\langle Q_0 \rangle = N A_{2\mu}$. The two-body expectation value in Eq. (14) is given in Eq. (6) and the three-body part is derived in Appendix A. Eq. (13) gives the average value for $\gamma$ while Eq. (14) probes its fluctuations from this average. Thus the information content of the two expressions for $\gamma$ are different and they compliment each other.

### III. CRANKING IN THE sd-IBM

In this section, we perform cranking calculations for a variety of sd-IBM Hamiltonians and compare the results for the dynamical MOI and $\gamma$ with the exact ones obtained from dynamical symmetries (SU(3) and O(6)), and from numerical diagonalization. For this purpose, we use a simple Hamiltonian with a quadrupole interaction and $d$-boson energy

$$H = -\kappa Q \cdot Q + \varepsilon \hat{n}_d.$$  

(15)

Following the convention, we denote the parameters of the quadrupole operator by $t_{202} = 1$ and $t_{222} = \chi$. The SU(3) limit is obtained when $\varepsilon = 0$ and $\chi = -\sqrt{7}/2$, and the O(6) limit when $\varepsilon = \chi = 0$. To test more realistic Hamiltonians, we use the middle value for $\chi (-\sqrt{7}/4)$, which leads to a better description of electromagnetic properties. Inclusion of the $d$-boson energy with $\varepsilon = 1.5 N \kappa$ improves, in addition, the moment of inertia systematics. The exact energy eigenvalues $E(L)$ are obtained from the Casimir operators in the case of the dynamical symmetries, and by numerical diagonalization of the Hamiltonian in the latter two cases.

For convenience in the variational problem, we set $x_{00} = 1$ and drop the subscript 2 from the quadrupole mean fields, i.e. $x_{2m} = x_m$. The normalization is then given by

$$N = 1 + x_0^2 + 2x_1^2 + 2x_2^2.$$  

(16)

The expectation value of the Hamiltonian $\langle N, x | H | N, x \rangle$, can be written from Eqs. (15) as

$$E(x) = -\kappa \big[ N(N - 1) (A_{20}^2 + 2A_{22}^2) + 5\langle \hat{n}_s \rangle + (\chi^2 + 1)\langle \hat{n}_d \rangle \big] + \varepsilon \langle \hat{n}_d \rangle.$$  

(17)

Here the quadratic forms $A_{2\mu}$ follow from Eq. (8) as

$$A_{20} = \frac{1}{N} \left[ 2x_0 - \sqrt{3/7} \chi (x_0^2 + x_1^2 - 2x_2^2) \right],$$

$$A_{22} = \frac{1}{N} \left[ 2x_2 + \sqrt{3/7} \chi (2x_0x_2 + \sqrt{3/2}x_1^2) \right].$$  

(18)
and the expectation values of $\hat{n}_s$ and $\hat{n}_d$ are

$$\langle \hat{n}_s \rangle = \frac{N}{N}, \quad \langle \hat{n}_d \rangle = \frac{N}{N} \left( 2x_0^2 + 2x_2^2 \right).$$  \hspace{1cm} (19)

From Eq. (11), the cranking term is given by

$$\langle \hat{I}_x \rangle = \frac{2N}{N} x_1 \left( \sqrt{6}x_0 + 2x_2 \right).$$  \hspace{1cm} (20)

In Fig. 1, we compare the cranking results for the dynamical MOI obtained from Eq. (11) with those obtained from Eq. (2) using the exact energy levels for $N = 10$ bosons. In the SU(3) and O(6) limits, the MOI is constant and given by $J_{\text{cr}}^{(2)} = 4/3\kappa = 200/3$ and $2/\kappa = 100 \hbar^2/\text{MeV}$, respectively. Note that both results are independent of $N$, and the constancy of MOI simply follows from the fact that $E(L)$ is quadratic in $L$ in both cases. The SCC leads to a constant MOI in the SU(3) limit, as expected from a rigid rotor, but deviates from the exact result by about 5%. The O(6) limit corresponds to a $\gamma$-unstable rotor for which cranking is not expected to work well. Not surprisingly, comparison of the cranking results for $J^{(2)}$ in Fig. 1 indicate a maximum deviation ($\sim 10\%$) from the exact result, as well as a small frequency dependence in MOI. We will comment on these deviations further when discussing the $N$ dependence of the results below. The case with $\chi = -\sqrt{7}/4$ falls in between the two dynamical symmetry results. The dynamical MOI increases with $\omega$ as in a typical deformed nucleus (Fig. 1), though the overall magnitude is still too large. The deviation between the cranking and the exact results in this case is comparable to that in the SU(3) limit, with the error getting smaller at higher frequencies. When a $d$-boson energy with $\varepsilon = 1.5N\kappa$ is included in the Hamiltonian, which fits the observed range of MOI data better, the agreement between the cranking and exact results improve markedly, especially at lower frequencies.

The SCC is a semi-classical theory and it would be exact in the classical limit when $N \to \infty$. Thus to understand the nature of discrepancies seen in Fig. 1 better, we need to study the $N$ dependence of the results. In Fig. 2, we show the SCC results for $J^{(2)}$ as a function of $N$ in the SU(3) and O(6) limits. Since the MOI is not constant in the O(6) limit, we have taken the value of $J^{(2)}$ at the middle-frequency for each $N$. The curves that trace the SCC results are obtained from

$$J^{(2)}_{\text{cr}} = J^{(2)}_{\text{ex}} \left( 1 + \frac{1}{2N} \right),$$  \hspace{1cm} (21)

in the SU(3) limit, and from

$$J^{(2)}_{\text{cr}} = J^{(2)}_{\text{ex}} \left( 1 - \frac{1}{N} \right),$$  \hspace{1cm} (22)

in the O(6) limit. The coefficients in Eqs. (21) and (22) are derived from a $1/N$ expansion of the SCC equation (1). It is clear from Fig. 2 and Eqs. (21, 22) that the SCC calculation of $J^{(2)}$ is correct to leading order but fails in higher orders in $1/N$ by generating spurious correction terms. A comparison of Eq. (17) with the accurate angular-momentum-projected result (6) confirms that the incorrect treatment of the $1/N$ terms in the SCC is the cause of the discrepancy. It is interesting to note that an agreement is obtained if one uses the Casimir operator of the SU(3) given by $C_2 = Q \cdot Q + (3/8) L \cdot L$, instead of just $Q \cdot Q$. In this case, the incorrect $1/N$ contribution from the $Q \cdot Q$ interaction is exactly canceled by the spurious contribution from the $L \cdot L$ term. Another interesting observation is that the best agreement of SCC with the exact results is achieved in the realistic case with $\chi = -\sqrt{7}/4$ and $\varepsilon = 1.5N\kappa$. This happens because the $1/N$ term is now dominated by the leading contribution from $\langle \hat{n}_d \rangle$, which is correctly treated in the SCC. The errors from $\langle \hat{n}_d \rangle$ contribute at the $1/N^2$ level, and these become apparent only at the high-rotational frequencies as is apparent in Fig. 1.

We next study the effects of triaxiality in SCC. It is well known that the energy surface of an $sd$-IBM Hamiltonian with one- and two-body interactions has an axially symmetric minima in the deformed phase (14). An exception occurs in the O(6) limit, where a $\gamma$-unstable shape develops. The SCC calculations in the O(6) limit give $30^\circ$ for both the average $\gamma$ (13) and its fluctuations (14) at all frequencies. Thus the SCC results are consistent with the description of the O(6) limit using a triaxial intrinsic state with $\gamma = 30^\circ$, which has a very shallow minimum in the $\gamma$ direction (14). Frequency independence of the results corroborates with the fact that the O(6) states remain $\gamma$-unstable at all spins. In Fig. 3 we show the evolution of the triaxiality angle $\gamma$ with the cranking frequency for the remaining three cases discussed above for three different boson numbers, $N = 10, 15, 20$. Results obtained from both Eq. (13) (solid line) and (14) (dashed line) are shown. The ground band in the SU(3) limit can be described exactly by angular momentum projection from an axially symmetric intrinsic state, therefore, both average $\gamma$ and its fluctuations should
vanish at all frequencies. The SCC results (Fig. 3 left) start with \( \gamma = 0 \) at low \( \omega \) but deviate from it systematically with increasing frequency. Although the situation appears to be improving with increasing \( N \), similar to the case in \( J^{(2)} \), in fact, this is merely due to the extension of the spectrum with \( N \) (\( \omega_{\text{max}} \propto N \)). If one scales out the \( N \) dependence (i.e., plots \( \gamma \) against \( \omega/N \)), then all the curves with different \( N \) overlap. Thus \( \gamma \) can be written as a power expansion in \( \omega/N \) with the leading (\( N \) independent) term being zero. This situation is similar to that encountered in the study of \( J^{(2)} \): the SCC gets the leading order term correctly (\( \gamma = 0 \)) but fails in higher-orders in \( 1/N \) by generating spurious terms in powers of \( \omega/N \). The fact that the incorrect \( 1/N \) terms in \( \gamma \) all depend on the cranking frequency makes the SCC results increasingly unreliable at higher frequencies. The onset of triaxiality observed at zero, and its fluctuations being slightly reduced from the ground state value at higher spins.

\[ \frac{\hbar}{
\begin{align*}
\langle H \rangle &= \frac{-\kappa_2 Q \cdot Q - \kappa_4 T_4 \cdot T_4 + \varepsilon_d \hat{n}_d + \varepsilon_g \hat{n}_g, \\
N &= 1 + x_{20}^2 + 2x_{21}^2 + 2x_{22}^2 + x_{40}^2 + 2x_{41}^2 + 2x_{42} + 2x_{43} + 2x_{44}^2, \\
E(x) &= -\kappa_2 [N(N-1)(A_{20}^2 + 2A_{22}^2) + 5\langle \hat{n}_s \rangle] + (1 + q_{22}^2 + q_{24}^2)(\hat{n}_d) + (5/9)(q_{24}^2 + q_{44}^2)(\hat{n}_g),
\end{align*}
\]

The expectation value of the Hamiltonian (23) follows from Eqs. (10) as

\[ \langle H \rangle = \frac{-\kappa_2 [N(N-1)(A_{20}^2 + 2A_{22}^2) + 5\langle \hat{n}_s \rangle] + (1 + q_{22}^2 + q_{24}^2)(\hat{n}_d) + (5/9)(q_{24}^2 + q_{44}^2)(\hat{n}_g)}{N} + \varepsilon_d \langle \hat{n}_d \rangle + \varepsilon_g \langle \hat{n}_g \rangle. \]

Here the quadrupole quadratic forms \( A_{2\mu} \) are given by

\[ \begin{align*}
A_{20} &= \frac{1}{N} \left[ 2x_{20} - \sqrt{2/7} q_{22} \left( x_{21}^2 + x_{22}^2 - 2x_{23}^2 \right) + 2\sqrt{2/21} q_{24} \left( \sqrt{3} x_{20} x_{40} + \sqrt{10} x_{21} x_{41} \right) \\
& \quad + \sqrt{5} x_{22} x_{42} \right] - (1/3) \sqrt{7} q_{44} \left( 10x_{40}^2 + 17x_{41}^2 + 8x_{42}^2 - 7x_{43}^2 - 28x_{44}^2 \right), \\
A_{22} &= \frac{1}{N} \left[ 2x_{22} + \sqrt{2/7} q_{22} \left( 2x_{20} x_{22} + \sqrt{3/2} x_{21}^2 \right) \\
& \quad + (2/3) \sqrt{14} q_{24} \left( x_{22} x_{40} + \sqrt{5} x_{22} x_{41} + \sqrt{15} x_{20} x_{42} + \sqrt{35} x_{21} x_{43} + \sqrt{70} x_{22} x_{44} \right) \right]
\end{align*} \]

IV. CRANKING IN THE sdg-IBM

In contrast to the sd-IBM, where numerical diagonalization is a routine task, the sdg-IBM already suffers from the large basis problem, and exact diagonalization is not possible for \( N > 11 \), that is, for most of the deformed nuclei. The \( 1/N \) expansion circumvents this problem but because it assumes axial symmetry, one cannot use it to address questions on triaxiality. Here we perform cranking calculations in the sdg-IBM to study the evolution of shapes with rotation without restriction to axial symmetry. For the Hamiltonian, we choose

\[ H = -\kappa_2 Q \cdot Q - \kappa_4 T_4 \cdot T_4 + \varepsilon_d \hat{n}_d + \varepsilon_g \hat{n}_g, \]
and the hexadecapole quadratic forms $A_{4\mu}$ by

$$A_{40} = \frac{1}{N} \left[ 2x_{40} + \sqrt{2/3}h_{22} \left( 3x_{20}^2 - 4x_{21}^2 + x_{22}^2 \right) - (2/\sqrt{71})h_{24} \left( 2\sqrt{5}x_{20}x_{40} + \sqrt{6}x_{21}x_{41} - 6\sqrt{3}x_{22}x_{42} \right) + \sqrt{2/1001}h_{44} \left( 9x_{40}^2 + 9x_{41}^2 - 11x_{42}^2 - 21x_{43}^2 + 14x_{44}^2 \right) \right],$$

$$A_{42} = \frac{1}{N} \left[ 2x_{42} + (1/\sqrt{7})h_{22} \left( \sqrt{6}x_{20}x_{22} - 2x_{21}^2 \right) + \sqrt{3/385}h_{24} \times \left( 6\sqrt{5}x_{22}x_{40} + 9x_{21}x_{41} - (8/\sqrt{3})x_{20}x_{42} - 5\sqrt{7}x_{21}x_{43} + 2\sqrt{14}x_{22}x_{44} \right) + \sqrt{5/1001}h_{44} \left( 6\sqrt{7}x_{42}x_{44} + 2\sqrt{7}x_{41}x_{43} - 11x_{40}x_{42} - 6x_{42}^2 \right) \right],$$

$$A_{44} = \frac{1}{N} \left[ 2x_{44} + h_{22}^2x_{22}^2 + (2/\sqrt{55})h_{24} \left( \sqrt{6}x_{22}x_{42} + \sqrt{21}x_{21}x_{43} + 2\sqrt{7}x_{20}x_{44} \right) + (1/\sqrt{143})h_{44} \left( 2\sqrt{14}x_{40}x_{44} + 2\sqrt{35}x_{41}x_{43} + 3\sqrt{5}x_{42}^2 \right) \right].$$  \(\text{(27)}\)

The one-body expectation values in Eq. (25) are given by Eq. (ref1 bsd) and

$$\langle \hat{n}_g \rangle = \frac{N}{N} \left( x_{40}^2 + 2x_{41}^2 + 2x_{42}^2 + 2x_{43}^2 + 2x_{44}^2 \right).$$ \(\text{(28)}\)

Finally, from Eq. (11) the cranking term is

$$\langle \hat{L}_z \rangle = \frac{2N}{N} \left[ x_{21} \left( \sqrt{6}x_{20} + 2x_{22} \right) + x_{41} \left( 2\sqrt{5}x_{40} + 3\sqrt{2}x_{42} \right) + x_{43} \left( \sqrt{14}x_{42} + 2\sqrt{2}x_{44} \right) \right].$$ \(\text{(29)}\)

In view of the numerous parameters in the \textit{sdg}-IBM, we limit our discussion to a realistic range tailored to data \[13\]. Accordingly, the quadrupole parameters \{\(q_2, q_{24}, q_{44}\)\} are scaled from their SU(3) values with a single factor \(q\) as suggested by microscopics \[14\]. The hexadecapole parameters \{\(h_{22}, h_{24}, h_{44}\)\} are determined from those of \(q_{jl}\) through the commutation condition

$$[\hat{h}, \hat{q}] = 0, \quad \hat{q}_{jl} = (j\ell\ell\ell\ell 20)q_{jl}, \quad \hat{h}_{jl} = (j\ell\ell\ell\ell 40)h_{jl},$$ \(\text{(30)}\)

which reproduce the available \(E4\) data reasonably well \[13\]. We adapt the realistic \textit{sd}-IBM parameters used in Fig. 1, \(\kappa_2 = -20\ \text{keV}, \ q = 0.5\) and \(\epsilon_d = 1.5N\kappa_2\), and use further, \(\epsilon_g = 4N\kappa_2\) and \(\kappa_4/\kappa_2 = 0.04\). Energy levels are very well described in the \textit{sdg}-IBM \[13\], therefore we do not dwell on a study of MOI apart from noting that all the SCC calculations of \(J^{(2)}\) exhibit the characteristic rise with increasing frequency seen in experimental spectra. We focus instead on the shape question which could not be addressed in the \(1/N\) expansion approach. With the parameter set described above, the SCC calculations of \(\gamma\) in the \textit{sdg}-IBM are very similar to those of the \textit{sd}-IBM with the realistic set of parameters (Fig. 3 right). Because the hexadecapole interaction is a relatively novel feature not used in the \textit{sd}-IBM, we briefly comment on its effect. Inclusion of the hexadecapole interaction does not cause any deviation from the axial shape but depending on its sign, it either decreases the fluctuations in \(\gamma\) (attractive) or increases them (repulsive) by a few degrees. This is very similar to the effect of changing the strength of the quadrupole interaction, in that, a larger \(\kappa_2\) leads to a deeper energy well in the \(\gamma\) direction, therefore reduces the fluctuations, and vice versa. In certain parametrizations where the boson energies are neglected, it is possible to obtain non-axial shapes in the \textit{sdg}-IBM \[13\]. However, once a \(g\)-boson energy of \(\epsilon_g \sim 1\ \text{MeV}\) is included, as demanded by the experimental spectra, such deviations from axial symmetry quickly disappear. In short, the congruence found between the \textit{sd}- and \textit{sdg}-IBM results with regard to the shape variable \(\gamma\) is a direct consequence of the fairly high \(g\)-boson energy, which limits the effect of \(g\) bosons to a perturbative range at low to medium spins.

\textbf{V. CONCLUSIONS}

We have tested the self-consistent cranking method using the exact IBM results obtained from dynamical symmetries and numerical diagonalization. The SCC results for the dynamic MOI are in good agreement with the exact ones, especially in realistic cases where the deviation is at most a few percent. The study of shapes using SCC, on the other
hand, remains problematic due to the generation of spurious frequency-dependent terms in shape variables, which become dominant at high frequencies. Nevertheless, SCC can give reliable information on evolution of shapes in the low to mid frequency range. Our study of shapes using SCC indicates that both the sd- and sdg-IBM with one- and two-body interactions retain the axial shape ($\gamma = 0$) with fluctuations around $10^6$, as long as the model parameters are restricted to a realistic range that reproduce the data. The only frequency dependence in shape variables is observed in the fluctuations in $\gamma$ which is slightly reduced with increasing frequency. These results suggest that if the triaxial effects are important and need to be included in the IBM, then the remedy should be sought in three-body interactions rather than $g$ bosons.

APPENDIX A: THREE-BODY OPERATORS

Here we derive the expectation value of the three-body quadrupole interaction in Eq. (4). The scalar product of the three quadrupole operators is defined as

$$ Q \cdot Q \cdot Q = [QQ]^{(2)} \cdot Q. \quad (A1) $$

The expectation value of this three-body term in the condensate state Eq. (2) is given by

$$ \langle Q \cdot Q \cdot Q \rangle = \frac{1}{N!} \sum_{\mu_1\mu_2\mu_3} (-1)^{\mu_3} 2\mu_2 [2\mu_3] \langle 0 | b^n Q_{\mu_3} Q_{\mu_2} Q_{\mu_1} Q - (b_1^\dagger)^n | 0 \rangle. \quad (A2) $$

Writing the quadrupole operators explicitly and commuting all the boson creation operators to the left, one obtains a three-body term, 3 two-body terms and a one-body term. Using boson calculus, the matrix elements of these normal ordered operators can be evaluated in a straightforward manner with the result

$$ \langle Q \cdot Q \cdot Q \rangle = \sum_{\mu_1\mu_2\mu_3} (-1)^{\mu_3} 2\mu_2 [2\mu_3] \sum_{j_1 j_2 j_3 l_1 l_2 l_3} \sum_{m_1 m_2 m_3 n_1 n_2 n_3} (-1)^{n_1 + n_2 + n_3} q_{j_1 l_1} q_{j_2 l_2} q_{j_3 l_3} $$

$$ \times \{ (j_1 m_1 l_1) (j_2 m_2 l_2) (j_3 m_3 l_3) [2 - \mu] $$

$$ \times \{ N(N - 1)(N - 2) x_{j_1 m_1} x_{j_2 m_2} x_{j_3 m_3} x_{l_1 n_1} x_{l_2 n_2} x_{l_3 n_3} $$

$$ + N(N - 1) x_{j_1 m_1} x_{j_2 m_2} x_{j_3 m_3} x_{l_1 n_1} x_{l_2 n_2} x_{l_3 n_3} \delta_{j_1 l_1} \delta_{m_1 m_3} + x_{j_1 m_1} x_{j_2 m_2} x_{j_3 m_3} x_{l_1 n_1} x_{l_2 n_2} x_{l_3 n_3} \delta_{j_1 l_1} \delta_{m_1 m_3} $$

$$ + N x_{j_1 m_1} x_{l_1 n_1} x_{l_2 n_2} x_{l_3 n_3} \delta_{j_2 l_2} \delta_{m_2 m_3} + x_{j_1 m_1} x_{j_2 m_2} x_{j_3 m_3} x_{l_1 n_1} x_{l_2 n_2} x_{l_3 n_3} \delta_{j_2 l_2} \delta_{m_2 m_3} $$

$$ + N x_{j_1 m_1} x_{l_1 n_1} x_{l_2 n_2} x_{l_3 n_3} \delta_{j_3 l_3} \delta_{m_3 m_2} + x_{j_1 m_1} x_{j_2 m_2} x_{j_3 m_3} x_{l_1 n_1} x_{l_2 n_2} x_{l_3 n_3} \delta_{j_3 l_3} \delta_{m_3 m_2} \} \}. \quad (A3) $$

The three-body part (the first term) is seen to involve a triple product of the one-body expectation values $A_{2\mu}$ defined in Eq. (8). In the effective two-body terms, three C-G coefficients can be summed to yield a 6 - $j$ symbol and a C-G coefficient. After some manipulations of the summation indices, all 3 terms can be shown to be equivalent. Finally, the sum of the four C-G coefficients in the effective one-body term gives a 6 - $j$ symbol. Thus, Eq. (A3) can be written compactly as

$$ \langle Q \cdot Q \cdot Q \rangle = N(N - 1)(N - 2) \sum_{\mu_1\mu_2\mu_3} (-1)^{\mu_3} 2\mu_2 [2\mu_3] A_{2\mu_3} A_{2\mu_2} A_{2-\mu_1} $$

$$ + 3N(N - 1) \sum_{\mu} (-1)^{\mu} A_{2\mu} A_{2-\mu} + N \sum_{lm} \tilde{q}_l x_{lm}^2, \quad (A4) $$

where we have introduced

$$ \tilde{q}_{jl} = 5 \sum_{i} (-1)^{l+j+i} \left\{ \begin{array}{ccc} j & l & 2 \\ 2 & 2 & i \end{array} \right\} q_{jl}, $$

$$ \tilde{\epsilon}_l = \frac{25}{2l+1} \sum_{ij} \left\{ \begin{array}{ccc} l & i & 2 \\ 2 & 2 & j \end{array} \right\} q_{il} q_{jl}, \quad (A5) $$

and $A_{2\mu}$ is obtained from $A_{2\mu}$ by replacing $q_{jl} \rightarrow \tilde{q}_{jl}$ in Eq. (8). Note that symmetry of $q_{jl}$ is retained, i.e., $q_{jl} = q_{lj}$. Using the fact that $A_{21} = A_{-1} = 0$ and $A_{22} = A_{-2}$, the sums in Eq. (A4) involving $A_{2\mu}$ can be carried out to yield
\[
\langle Q \cdot Q \cdot Q \rangle = N(N-1)(N-2) \sqrt{2/7}(-A_{20}^2 + 6A_{22}^2)A_{20} + 3N(N-1)(\hat{A}_{20}A_{20} + 2\hat{A}_{22}A_{22} + N \sum_{lm} \tilde{\varepsilon}_l x_{lm}^2),
\]
(A6)

In the case of the sd-IBM, \(A_{20}\) and \(A_{22}\) are given in Eq. (B8). The contracted parameters in Eq. (A5) become

\[
\hat{q}_{02} = \chi, \quad \hat{q}_{22} = 1 - 3\chi^2/14,
\]
\[
\hat{\varepsilon}_0 = 5\chi, \quad \hat{\varepsilon}_2 = 2\chi - 3\chi^2/14.
\]

(A7)

Using these values of \(\hat{q}_{jl}\), one obtains for \(\hat{A}_{20}\) and \(\hat{A}_{22}\)

\[
\hat{A}_{20} = \frac{1}{N} \left[ 2\chi x_0 - \sqrt{2/7}(1 - 3\chi^2/14)(x_0^2 + x_1^2 - 2x_2^2) \right],
\]
\[
\hat{A}_{22} = \frac{1}{N} \left[ 2\chi x_2 + \sqrt{2/7}(1 - 3\chi^2/14)(2x_0x_2 + \sqrt{3/2}x_1^2) \right],
\]

(A8)

In the sdg-IBM, these parameters are given by

\[
\hat{q}_{02} = q_{22}, \quad \hat{q}_{22} = 1 - \frac{3}{14}q_{22}^2 + \frac{2}{7}q_{24}^2, \quad \hat{q}_{24} = \frac{2}{7}q_{22}q_{24} - \frac{5\sqrt{22}}{42}q_{24}q_{44},
\]
\[
\hat{q}_{44} = \frac{5\sqrt{22}}{42}q_{24}^2 - \frac{65}{42\sqrt{22}}q_{44}^2,
\]
\[
\hat{\varepsilon}_0 = 5q_{22}, \quad \hat{\varepsilon}_2 = 2q_{22} - \frac{3}{14}q_{22}^3 + \frac{4}{7}q_{22}q_{24}^2 + \frac{5\sqrt{22}}{42}q_{24}^3q_{44},
\]
\[
\hat{\varepsilon}_4 = \frac{10}{63}q_{22}q_{24}^2 + \frac{25\sqrt{22}}{189}q_{24}^2q_{44} - \frac{325}{378\sqrt{22}}q_{44}^4.
\]

(A9)

\[\text{FIG. 1. Comparison of the cranking calculations of the dynamical moment of inertia in the } sd\text{-IBM (lines) with the exact results obtained from the dynamical symmetries SU(3) and O(6) (filled circles), and numerical diagonalization (} \chi = -\sqrt{7}/4 \text{ with } \varepsilon = 0 \text{ and } \varepsilon = 1.5N\kappa \text{) (open circles). In all cases, } N = 10 \text{ and } \kappa = -20 \text{ keV are used.}\]

\[\text{FIG. 2. Boson number dependence of the cranking dynamical moment of inertia in the SU(3) and O(6) limits of the } sd\text{-IBM (circles). The lines that trace the circles are obtained from Eq. (21) in the SU(3) case and from Eq. (22) in the O(6) case.}\]
FIG. 3. Cranking calculations of the triaxiality angle $\gamma$ in the sd-IBM for the three cases shown in Fig. 1 for $N = 10, 15, 20$. The solid lines indicate average $\gamma$ obtained from Eq. (13) and the dashed lines correspond to its fluctuations given by Eq. (14).
$J^{(2)} (\hbar^2/\text{MeV})$

- O(6)
- $\chi = \chi_{SU3}/2$
- SU(3)
- $\epsilon/\kappa N = 1.5$
The diagrams illustrate the comparison between exact and cranking calculations for two different limits: SU(3) and O(6) limits. The SU(3) limit shows a decreasing trend, while the O(6) limit shows an increasing trend. The cranking calculations are represented by the solid lines, and the exact calculations are shown by the horizontal lines.
\[ \chi = \chi_{SU3} \]

\[ \chi = \chi_{SU3} / 2 \]

\[ \chi = \chi_{SU3} / 2 \]

\[ \varepsilon / \kappa N = 1.5 \]

\[ N = 10, 15, 20 \]

\[ h\omega \text{ (MeV)} \]

\[ \gamma \text{ (degrees)} \]
