ABSTRACT: We consider two approaches to estimate and characterise the theoretical uncertainties stemming from the missing higher orders in perturbative calculations in Quantum Chromodynamics: the traditional one based on renormalisation and factorisation scale variation, and the Bayesian framework proposed by Cacciari and Houdeau. We estimate uncertainties with these two methods for a comprehensive set of more than thirty different observables computed in perturbative Quantum Chromodynamics, and we discuss their performance in properly estimating the size of the higher order terms that are known. We find that scale variation with the conventional choice of varying scales within a factor of two of a central scale gives uncertainty intervals that tend to be somewhat too small to be interpretable as 68% confidence-level-heuristic ones. We propose a modified version of the Bayesian approach of Cacciari and Houdeau which performs well for non-hadronic observables and, after an appropriate choice of the relevant expansion parameter for the perturbative series, for hadronic ones too.

1 Introduction

Precision phenomenology of the kind aimed for by the Large Hadron Collider (LHC) physics program requires accurate and reliable theoretical predictions to be compared to an ever increasing range of high precision experimental measurements. Once theoretical and experimental uncertainties become of comparable size, it is crucial to be able to characterise quantitatively the relevance of missing higher order terms in perturbative calculations.
In Quantum Chromodynamics (QCD), which we take as a model here given its central role in LHC physics, theoretical uncertainties stemming from missing higher orders in the perturbative series are usually estimated by varying the unphysical renormalisation and factorisation scales that appear in the calculation of cross sections and decay rates. This approach has served the QCD community well for more than thirty years, and can still be regarded as the most effective way to quickly estimate the missing higher order uncertainties (MHOUs). It suffers, however, from some drawbacks. Chiefly among them the fact that its uncertainty intervals cannot be characterised in a statistically meaningful way and therefore cannot be combined easily with, for example, likelihood profiles for other uncertainties, for instance of experimental origin.

One of us (MC) and N. Houdeau tried in [1] to overcome this limitation by proposing to estimate MHOUs in a Bayesian context, so as to obtain a statistically meaningful posterior distribution for the probability density profile of the uncertainty interval. The Cacciari-Houdeau approach led to a model (henceforth CH) that relies on simple priors that, at their core, partly mimic assumptions that are anyway implicitly made when one employs the scale-variation method. We refer to [1] for a more detailed description of the CH approach and its underlying Bayesian character, and e.g. to [2–4] for some examples of applications of its results. In a context of estimation of MHOUs, we also point out the different but possibly complementary approach of [5] that focuses on a mathematically motivated approximate completion of a perturbative series.

The purpose of this paper is twofold. On the one hand, we revisit the Bayesian CH model, and propose a modified version (which we will denote CH) which will trade some of the simplicity of the original CH model for a better adaptability to a broader class of observables, namely those related to processes with hadrons in the initial state. On the other hand, we study the results of both the scale-variation and the CH model on a large number of perturbatively calculated observables, so as to be able to assess their performance in a (frequentist) statistically meaningful way. For the scale-variation approach, this means that we can attempt to characterise a posteriori its uncertainty intervals in terms of some confidence level that they correctly describe the MHOUs. For the CH model, this study allows us to either assess whether the Degree of Belief (DoB) associated to the uncertainty intervals is correct or, where needed, to estimate the appropriate expansion parameter of the perturbative series that ensures that this be the case.

The paper is structured as follows. Section 2 reviews the scale-variation approach and the Bayesian method introduced in [1], and describes the modifications to the CH model that lead to the formulation of the CH approach used in this paper. Section 3 describes the methodology that we have followed in our study of the performance of the scale-variation and the CH approach, introduces the list of calculated observables used in the survey, and presents our results. Section 4 compares the results of the scale-variation and the CH method for the determination of MHOUs for some benchmark processes that we consider either particularly relevant for LHC phenomenology or simply quite iconic, namely $e^+e^− \rightarrow$ hadrons, Higgs decay to two gluons and to two photons, $W$ and $Z$ production in $pp$ collisions, $pp \rightarrow t\bar{t}$ and Higgs production in proton-proton collisions. A concluding section follows, while a few appendices collect technical details and the numerical values of the perturbative coefficients of the observables used in the survey and the benchmarking.
2 Estimations of theoretical uncertainties

In this section, we introduce and describe two different approaches to the estimation of the uncertainty stemming from the missing higher orders of a perturbatively calculated observable:

- the scale-variation approach, which involves varying the unphysical renormalisation and factorisation scales that appear in higher order perturbative calculations within a given range around a chosen central value;
- the Bayesian approach introduced by Cacciari and Houdeau in [1], with the modifications discussed below.

In the following, we review how these two approaches work, and also set the appropriate notations.

2.1 Uncertainty estimation by scale variation

The truncated perturbative expansion of an arbitrary observable \( O \) calculated up to a fixed order \( k \) as a power series expansion in \( \alpha_s \),

\[
O_k(Q, \mu) = \sum_{n=l}^{k} \alpha_s^n(\mu)c_n(Q, \mu),
\]

contains a residual, higher-order dependence on the renormalisation and/or factorisation scales, here collectively denoted by \( \mu \).

The standard approaches to estimate the MHOUs are all based on the idea of varying the scale(s) \( \mu \) in an interval \([Q/r, rQ]\), where \( r \) is an arbitrary factor often chosen to be equal to 2, and \( Q \) is a typical hard scale of the process. The values of the observable obtained at different scales are then used to derive an uncertainty interval. Different recipes can be used to implement this prescription. Writing this interval as \([O_k^-, O_k^+]\) around \( O_k \) (not necessarily centred around it), the most common choices are:

1. \[
O_k^- = \min \{O_k(Q, Q/r), O_k(Q, rQ), O_k(Q, Q)\}, \quad O_k^+ = \max \{O_k(Q, Q/r), O_k(Q, rQ), O_k(Q, Q)\}.
\]

2. \[
O_{k^+} = \min_{\mu \in [Q/r, rQ]} \{O_k(Q, \mu)\}, \quad O_{k^-} = \max_{\mu \in [Q/r, rQ]} \{O_k(Q, \mu)\}.
\]

3. \[
O_{k^\pm} = O_k \pm \frac{\delta_k}{2},
\]

where we have defined

\[
\delta_k \equiv |O_k(Q, rQ) - O_k(Q, Q/r)|.
\]

4. Same as eq. (2.4) but with

\[
\delta_k \equiv \max_{\mu \in [Q/r, rQ]} \{O_k(Q, \mu)\} - \min_{\mu \in [Q/r, rQ]} \{O_k(Q, \mu)\}.
\]
Generalisation to the case of two or more scales is straightforward and follows along the same lines. The prescription which is probably most commonly used (see e.g. the QCD review in [6]), and which we will also use in our study, is an extension of eq. (2.2), i.e. varying both the renormalisation and the factorisation scale ($\mu_r$ and $\mu_f$) as shown there, but with the additional constraint $1/r \leq \mu_r/\mu_f \leq r$, to avoid the appearance of unnaturally large logarithms.\footnote{To the best of our knowledge, this additional constraint was first adopted in [7], following a suggestion by Stefano Catani.}

The main problem with the scale-variation approach is that it does not provide a probability distribution for the uncertainty interval, which therefore has no statistical meaning. It is also worth noting that the common choice $r = 2$ is merely a convention, and that the choice of the central scale around which to perform the variation is also largely arbitrary. In fact, in some cases this central scale is deliberately chosen away from the characteristic scale of the process to satisfy other criteria. This is for instance the case for Higgs production in gluon fusion, where the central scale is often chosen equal to $m_H/2$ to mimic the result obtained when performing soft-gluon resummation [8], and because around this value, the cross section shows reduced sensitivity to the scale choice and an improved convergence of the perturbative series [9].

2.2 The Cacciari-Houdeau Bayesian approach

The approach of Cacciari and Houdeau [1] uses a Bayesian framework to evaluate MHOUs. It makes assumptions on the behaviour of the coefficients of a series of the form

$$O_k \equiv O_k(Q, Q) = \sum_{n=l}^{k} \alpha_s^n(Q)c_n(Q, Q) = \sum_{n=l}^{k} \alpha_s^n c_n,$$

(2.7)

where the unphysical scales $\mu$ have been set to the central value $Q$, and we have implicitly defined $\alpha_s \equiv \alpha_s(Q)$ and $c_n \equiv c_n(Q, Q)$. These assumptions are encoded into specific Bayesian priors (detailed in [1]) and in the choice of the expansion parameter, taken here to be $\alpha_s$. They allow one to determine an uncertainty density profile (the posterior of the model) in the form of a conditional probability density for the remainder of the series,$^2$

$$\Delta_k \equiv \sum_{n=k+1}^{\infty} \alpha_s^n c_n,$$

given the known perturbative coefficients, $\{c_l, \ldots, c_k\}$. Assuming that the dominant contribution to the remainder comes from the first unknown order, i.e. $\Delta_k \simeq \alpha_s^{k+1} c_{k+1}$, one can derive [1] a simple analytic expression for the conditional density,

$$f(\Delta_k|c_l, \ldots, c_k) \simeq \left(\frac{n_c}{n_c+1}\right) \frac{1}{2\alpha_s^{k+1}\bar{c}(k)} \left\{ \begin{array}{ll}
1 & \text{if } |\Delta_k| \leq \alpha_s^{k+1}\bar{c}(k) \\
\frac{\alpha_s^{k+1}\bar{c}(k)}{|\Delta_k|}^{n_c+1} & \text{if } |\Delta_k| > \alpha_s^{k+1}\bar{c}(k)
\end{array} \right.,$$

(2.8)

where $\bar{c}(k) \equiv \max(|c_l|, \ldots, |c_k|)$ and $n_c$ is the number of known perturbative coefficients. From this expression, one can appreciate the characteristics of the posterior distribution for this model: a central plateau with power suppressed tails.

$^2$The use of an upper limit for the summation at infinity in $\Delta_k$ should be considered as merely symbolic, QCD series being asymptotic. In practice, the remainder that we will be dealing with will be limited to the region of apparent convergence of the series, and will usually be approximated by its first term.
The existence of such a probability density distribution for the uncertainty interval represents the main difference with the scale-variation approach which only gives an interval without a density profile.

Given the conditional density in eq. (2.8), it is possible to compute the smallest credibility interval for $\Delta_k$ with a degree of belief (DoB) equal to $p\%$ (i.e. such that $\Delta_k$ is expected with $p\%$ credibility to be contained within the interval $[-d^{(p)}_k, d^{(p)}_k]$),

$$d^{(p)}_k = \begin{cases} \alpha_k^{k+1}c_{(k)} \frac{n_c+1}{n_c} p\% & \text{if } p\% \leq \frac{n_c}{n_c+1} \\ \alpha_k^{k+1}c_{(k)} [(n_c+1)(1-p\%)]^{(-1/n_c)} & \text{if } p\% > \frac{n_c}{n_c+1}. \end{cases}$$  \hspace{1cm} (2.9)

### 2.3 The modified Cacciari-Houdeau approach (CH)

The CH model described above relies on a specific form of the perturbative expansion, namely eq. (2.7). As a result, its estimate for the uncertainty is not invariant under a rescaling of the expansion parameter from $\alpha_s$ to $\alpha_s/\lambda$. While working on this project we made a number of attempts to reformulate the model in a rescaling-invariant way. Ultimately, none of them turned out to be satisfactory, to the extent that each required formulating priors much too informative, which shaped excessively the final posterior. Instead, we eventually settled on a slightly modified version of the CH model. In this modified model, henceforth denoted as CH, we rewrite the perturbative expansion of eq. (2.7) in the form

$$O_k = \sum_{n=l}^{k} \alpha_s^n (n-1)! \frac{\lambda^n c_n}{(n-1)!} \equiv \sum_{n=l}^{k} \left( \frac{\alpha_s}{\lambda} \right)^n (n-1)! b_n,$$

with

$$b_n \equiv \frac{\lambda^n c_n}{(n-1)!}, \hspace{1cm} (2.11)$$

and submit the new coefficients $b_n$ to the same priors originally used for the $c_n$ in the CH model. This leads to the following expressions for the probability density profile for the remainder function $\Delta_k$

$$f(\Delta_k|b_1, \ldots, b_k) \simeq \left( \frac{n_c}{n_c+1} \right) \frac{1}{2k!(\alpha_s/\lambda)^{k+1}b_{(k)}} \begin{cases} 
\frac{1}{k!(\alpha_s/\lambda)^{k+1}b_{(k)}} \left( \frac{k!(\alpha_s/\lambda)^{k+1}b_{(k)}}{|\Delta_k|} \right)^{n_c+1} & \text{if } |\Delta_k| \leq k! \left( \frac{\alpha_s}{\lambda} \right)^{k+1} b_{(k)} \\
\frac{1}{k!(\alpha_s/\lambda)^{k+1}b_{(k)}} [(n_c+1)(1-p\%)]^{(-1/n_c)} & \text{if } |\Delta_k| > k! \left( \frac{\alpha_s}{\lambda} \right)^{k+1} b_{(k)} 
\end{cases}$$

and the credibility interval

$$d^{(p)}_k = \begin{cases} 
k! \left( \frac{\alpha_s}{\lambda} \right)^{k+1} b_{(k)} \frac{n_c+1}{n_c} p\% & \text{if } p\% \leq \frac{n_c}{n_c+1} \\
k! \left( \frac{\alpha_s}{\lambda} \right)^{k+1} b_{(k)} [(n_c+1)(1-p\%)]^{(-1/n_c)} & \text{if } p\% > \frac{n_c}{n_c+1}. \end{cases}$$  \hspace{1cm} (2.12)

The introduction of the $(n-1)!$ term in the expansion, which represents the main modification with respect to the original CH model, can be justified on the ground that such a factor is expected to appear in higher order perturbative calculations, e.g. those in the large-$\beta_0$ limit and in connection with renormalon contributions [11–14].

---

For a detailed description of the reformulations considered in the course of the present work, and eventually discarded, we refer the interested reader to [10].
The optimal value for the rescaling factor $\lambda$ can be determined empirically by observing how the model fares in predicting MHOUs for observables for which higher order perturbative computations are available. In section 3, we will present such a determination of $\lambda$ from a study based on a comprehensive set including more than thirty observables. This method of determining $\lambda$ brings some frequentist contamination into the Bayesian approach. We consider this drawback acceptable at the present stage, but we note that one could in principle further improve the model by introducing an additional prior for the value of $\lambda$ and thus avoid the frequentist contamination. The frequentist study on $\lambda$ performed in this work can then perhaps be used as a guide for the formulation of such an additional prior.

### 2.3.1 Extension to hadronic observables

The original CH model was formulated focusing on observables in processes without hadrons in the initial state, and its extension to observables with initial state hadrons is potentially not straightforward. A generic hadronic observable (e.g. a total cross section) can be written as a convolution integral

$$O_k(\tau, Q) = \mathcal{L}(Q) \otimes \sum_{n=l}^{k} \alpha_s^n C_n(Q)$$

where $\mathcal{L}$ is the parton-parton luminosity, $C_n(Q)$ is the hard-scattering coefficient function, $\tau$ is an appropriate hadronic scaling variable, $Q$ is the characteristic energy scale of the process and $\otimes$ denotes a generic convolution in the space of the hadronic scaling variables (not explicitly shown on the right hand side of the equation). The unphysical renormalisation and factorisation scales are taken to be equal to $Q$ as in the non-hadronic case, and they are not explicitly shown. In eq. (2.14), the perturbative coefficient functions $C_n$ are usually distributions, and not simple numbers like the coefficients $c_n$ in the perturbative expansion of the non-hadronic observables. This means that it is not possible to directly apply the CH method described in section 2.3 to hadronic observables. This problem can be overcome in two ways.

1. A first approach is to express the hadronic observable as a series expansion whose coefficients include the convolution with the parton-parton luminosities, i.e. to rewrite eq. (2.14), in analogy with the non-hadronic case, in the form

$$O_k(\tau, Q) = \mathcal{L}(Q) \otimes \sum_{n=l}^{k} \alpha_s^n C_n(Q) \equiv \sum_{n=l}^{k} \left( \frac{\alpha_s}{\lambda_h} \right)^n (n - 1)! \lambda_h^n H_n(\tau, Q)$$

where we have defined

$$H_n(\tau, Q) \equiv \frac{\lambda_h^n}{(n - 1)!} h_n \equiv \frac{\lambda_h^n}{(n - 1)!} \mathcal{L}(Q) \otimes C_n(Q).$$

We now denote the rescaling parameter with $\lambda_h$, rather than $\lambda$, to stress the fact that its value is a priori potentially different from the one used in the case of non-hadronic observables. We then proceed like in the non-hadronic case, submitting the expansion coefficients $H_n$ to the same Bayesian priors used in the non-hadronic case.
This approach is based on the assumption that the contribution coming from the non-perturbative physics encoded in the parton-parton luminosity is roughly the same at each perturbative order, or more generally that its presence does not spoil the assumptions of the model. This approach has been adopted in some of the papers that have used the CH approach in its original formulation, e.g. [3, 4].

2. A second approach is based on rewriting the observable in Mellin space, in the form

\[ O_k(N, Q) = \mathcal{L}(N + 1) \sum_{n=1}^{k} \left( \frac{\alpha_s}{\lambda_h} \right)^n (n - 1)! B_n(N, Q), \]  

(2.17)

where

\[ B_n(N, Q) \equiv \frac{\lambda_h^n}{(n - 1)!} \int_0^1 dx x^{N-1} C_n(x, Q) \]  

(2.18)

is the Mellin transform of the short-distance coefficient function \( C_n \), rescaled by the factor \( \lambda_h^n/(n - 1)! \) introduced in CH, and \( \mathcal{L}(N + 1) \) is the Mellin transform of the parton-parton flux. We then observe that, if the Mellin inversion integral can be shown to be dominated by a single Mellin moment \( O_k(N_0, Q) \), one can simply apply the Bayesian priors of the CH approach to the short-distance coefficients \( B_n(N_0, Q) \), which are ordinary numbers, and thus determine the uncertainty for the dominant moment series. This uncertainty can then be translated back to the uncertainty on the full result by an appropriate rescaling. This approach is viable because one can show that at least in some cases (see e.g. [15, 16]), such a dominant Mellin moment exists and gives a good approximation to the full result.

The main limitation of this approach, which a priori would be preferred because it eliminates the possible contamination due to non-perturbative physics, is that it relies on the predominance of not only a single Mellin moment but also a single production channel (e.g. gluon-gluon fusion in Higgs production at the LHC) at all orders. If this is not the case, the need to reweigh the various dominant Mellin moments in the different parton channels will reintroduce contamination from non-perturbative physics. A second, practical, limitation is that perturbative results are rarely available in Mellin moment space from public codes, limiting the straightforward application of this method to very few cases. Because of these limitations we use the first approach, i.e. the convolution, as our main tool in this paper, but we also present in appendix B two case studies for the Mellin-moment method.

3 Global survey

In this section, we assess the performance of the scale-variation procedure and of the CH approach by studying how well they estimate the MHOUs when applied to a wide set of observables. For every observable in the set we consider two quantities:

1. the size of the uncertainty predicted at a given perturbative order \( k \) by the approach under consideration;

2. the known perturbative result for the same observable at order \( k + 1 \).
For each of the methods, we then determine its global success rate in predicting the missing higher order uncertainties at order $k$, defined as fraction of observables for which the result of the calculation at order $k+1$ falls within the uncertainty interval predicted by the model for the order $k$ computation.

In the case of the scale-variation method, we study the behaviour of the global success rate as we vary the scaling factor $r$ defined in section 2.1. The observed success rate can then be used to assign an a posteriori heuristic confidence level (CL) to the uncertainty intervals obtained with a given value of $r$.

In the case of the CH Bayesian approach, we repeat the analysis described above for various values of $\lambda$ and, since we now have a probabilistic interpretation of the resulting uncertainty intervals, various Degrees of Belief (DoB). This allows us to determine the optimal value of $\lambda$ to be used in CH, defined as the value of $\lambda$ for which the model has a global success rate which is closest to the requested DoB, for every possible DoB.

3.1 Setup

We perform two separate analyses, one for observables in processes without hadrons in the initial state (non-hadronic observables) and one for observables in processes with hadrons in the initial state (hadronic observables).

The non-hadronic observables considered in our analysis are listed in table 1. For each observable, we show the leading order in $\alpha_s$, the maximum known order in $\alpha_s$ and a reference to the original literature from which we have extracted the values of the perturbative coefficients. When the leading order contribution for these observables is entirely electroweak in nature, we do not include the first coefficient $c_0$ in the analysis when using the CH approach, as was done in [1]. This is because we are interested in a perturbative expansion in terms of the strong coupling.

The observables included in our hadronic analysis are listed in table 2, where again we show the leading order in $\alpha_s$, the highest known order in $\alpha_s$ and a reference to the code implementing the computation that we used to evaluate the perturbative coefficients. In this case, the leading order coefficient (i.e. the first one) is always retained for the analysis with the CH approach, independently of its perturbative order in the strong coupling. In order to avoid biasing the analysis by using different parton distribution functions (PDFs) at different orders, we always use the same NNLO PDFs for all perturbative orders, with the exception of the scale-variation study shown in the right plot of figure 2.

All the coefficients and the specific parameters for the calculations are given in appendix A, in tables 5 and 6. For all our analyses, we have used a private Mathematica code.

3.2 Results

3.2.1 Scale variation

In this section, we study the performance of the standard scale-variation approach. An outcome of this analysis is the determination of a heuristic confidence level (CL) for the

\footnote{When this first coefficient is of zeroth order we set the $(n-1)!$ term equal to one in the perturbative expansion in eq. (2.15).}

uncertainty intervals given by scale variation, as a function of the scaling factor $r$ that sets the range over which the scales are varied, $\mu \in [Q/r, rQ]$.

In the non-hadronic case, we compare two of the prescriptions given in section 2.1, which are supposedly the most widely used ones: a) take the maximum and the minimum of the cross sections obtained with $\mu = rQ$ or $\mu = Q/r$, as explained in eq. (2.2); b) take the maximum and the minimum while scanning the whole interval of scales between $Q/r$ and $rQ$, as explained in eq. (2.3). Results for the first prescription (i.e. using only the extreme values) are given in the left plot of figure 1. At LO, the heuristic CL of the scale-variation uncertainty intervals for the conventional $r = 2$ value is of the order of 50%, and it reaches a 68% level for $r$ close to 4. For larger values of $r$, the CL stabilises around 80%. At NLO, the CL is still of the order of 50% at $r = 2$, but it increases more rapidly with $r$ than at LO, and it is already around 68% for $r \approx 2.5$–3. For higher values of $r$, it stabilises around 80%. Results for the second scale-variation prescription (i.e. doing a full scan) are given in the right plot of figure 1. While the LO results are identical to those of the first prescription,

Table 2. List of hadronic observables used in the global survey.

the NLO heuristic CLs are significantly larger for $r \geq 4$, reaching 100% at $r = 5$. This is likely explained by the fact that at NLO accuracy, a full scan can capture better the overall variation of the usually non-monotonic scale dependence than the evaluation of two or three fixed points only.

We have also examined scale-variation uncertainties in the case of hadronic observables. Since hadronic cross sections depend on two scales, the factorisation and renormalisation scale, we vary them independently to obtain the scale-variation interval. As often done in literature, we do not perform a full scan (too computationally expensive) but rather evaluate the observables only at the centre and at the extremes of a scale range, avoiding combinations that generate large logarithms, as explained at the end of section 2.1. Figure 2 shows the results of the analysis of the full set of hadronic observables. We have calculated the cross sections both using NNLO PDFs at each order (left plot) and using order-matched PDFs (right plot), i.e. using LO PDFs for the LO computation, NLO ones at NLO, etc.\footnote{We have used NNPDF 2.1 [36] at LO, and NNPDF 2.3 [37] at NLO and NNLO.} At each perturbative order, the two choices are equivalent up to higher order terms. In both cases, we see that, as common wisdom dictates, the LO scale-variation uncertainty fails to capture the size of the NLO correction. At NLO, the two prescriptions differ qualitatively in their performance. When using always NNLO PDFs, we can associate a 40% heuristic CL to the standard scale variation with $r = 2$. The 68% CL level is attained around $r = 3$, and the CL then stabilises around 90% CL for $r \geq 3.5$. When using order-matched PDFs, on the other hand, we obtain a very small heuristic CL (less than 30%) for $r \leq 3$. The CL reaches 68% for $r$ just over 4 and then stabilises around 80% for larger values of $r.$
Fraction of observables whose known higher order is found to be contained within the uncertainty interval given by scale variation between $\mu = Q/r$ and $\mu = rQ$. Left plot: only the extremes and the central value of the $[Q/r, rQ]$ interval are used. Right plot: the full $[Q/r, rQ]$ interval is scanned.

Figure 2. Fraction of observables whose known higher order is found to be contained within the uncertainty interval given by renormalisation and factorisation scale variation between $\mu_{r,f} = Q/r$ and $\mu_{r,f} = rQ$ with the constraint $1/r \leq \mu_{r}/\mu_{f} \leq r$. Only the seven points at the extremes and at the centre of the scale-variation interval are used. Left plot: NNLO-evolved PDFs are used with all perturbative orders. Right plot: PDFs evolution order is matched with the perturbative order of the observable.

These two analyses for hadronic observables suggest that in the scale-variation approach one may wish to use a rescaling factor $r \sim 3-4$ in order to obtain a reasonably conservative uncertainty interval, with a heuristic CL at least as large as 68%.

3.2.2 The modified Cacciari-Houdeau model (CH)

For each of the sets of observables listed in tables 1 and 2, we have performed an analysis of the performance of the CH model in estimating the MHOUs. In this case, a parameter of the model is the $\lambda$ ($\lambda_h$) factor that defines the effective expansion parameter of the

---

\[ \text{A rescaling factor } r \text{ larger than 2 for estimating MHOUs through scale variation has been used in some cases in phenomenological analyses. For instance, it has been advocated in the case of Higgs production in gluon fusion in [38, 39].} \]
p perturbative series as written in the model, see eq. (2.10) and eq. (2.15). As far as the size of the uncertainty intervals is concerned, the parameter \( \lambda (\lambda_h) \) plays a role analogous to that of \( r \) in the scale-variation approach: the final result will depend on its value. However, since in the Bayesian model the widths of the uncertainty intervals are associated with properly defined credibility values, one can explicitly determine the optimal value for \( \lambda (\lambda_h) \) by requiring that the model performs as expected, i.e. that the observed global success rate corresponds to the DoB of the uncertainty intervals used in the analysis.

We first study the non-hadronic case. We show the results of this analysis graphically in figure 3 in two different and complementary ways. Both analyses use observables calculated at perturbative orders ranging from LO to N\(^3\)LO, for a total of 37 tests performed using the numerical coefficients given in table 5 in appendix A. The histogram in figure 3 (left) is obtained by varying the DoB between 0.05 and 0.95 in steps of 0.01 (the uncertainty interval returned by CH varies of course accordingly). For each DoB value, we determine the \( \lambda \) value which gives the best agreement with the condition DoB = global success rate. The resulting \( \lambda \) values are plotted in a histogram. At LO, the preferred values for \( \lambda \) can be seen to be between 0.6 and 0.9, while at NLO, the histogram shows a preference for the range 0.9–1.1. The plot in figure 3 (right) shows instead how DoB and success rate compare for different values of \( \lambda \) in a global analysis of LO, NLO and NNLO observables. We see that for values of \( \lambda \) in the 0.9–1.1 range, the requested DoB agrees well with the observed success rate of the uncertainty prediction.\(^7\) This is in agreement with the result that we obtain from the histogram analysis.

We perform the same analysis for the hadronic observables set using the coefficients given in table 6 in appendix A. Figure 4 (left) shows the histogram of the optimal values of \( \lambda_h \) for the DoB scan made using the full set of hadronic observables. The histogram

\(^7\)This frequentist-like determination of \( \lambda \) is itself subject to an uncertainty due to the finite size of the set of observables that we have used, which results in a statistical error on the observed success rate (see appendix C for a quantitative analysis). This statistical error is displayed as a grey band in figure 3 (right). One can see how it roughly translates into a limiting precision of \( \pm 0.2 \) in the determination of \( \lambda \).
peaks around $\lambda_h \simeq 0.5$ at NLO, which is smaller than the preferred $\lambda$ value obtained from
the analysis of non-hadronic observables. In figure 4 (right) we plot the success rate as a
function of the DoB of the $\text{CH}$ intervals for various values of $\lambda_h$ for all hadronic observables
at LO and NLO. We observe that the preferred value of $\lambda_h$ oscillates between 0.5 and 0.6
according to the requested DoB. Since we are mainly interested in determining 68% and
95% DoB intervals, we choose a value of $\lambda_h$ equal to 0.6 as our best estimate, since it
appears to be the one for which the model performs better in this DoB range.

The results of the analyses presented in this section allow us to define the optimal
values for the parameters in the $\text{CH}$ model as follows: we use a parameter $\lambda = 1$ when
considering non-hadronic observables, while we use $\lambda_h = 0.6$ when considering hadronic
observables.\footnote{It may be tempting to speculate that the smaller value of $\lambda$ in the hadronic case (and therefore a larger
effective expansion parameter for the series) may be explained by the generally larger number of gluons
involved in these processes, and therefore by an expansion parameter closer to $\alpha_s C_A$ than to $\alpha_s C_F$, but we
will refrain from doing so.}

4 Benchmark processes

In this section, we compare the results obtained when computing MHOUs using either
the $\text{CH}$ or the scale-variation prescription for a set of benchmark processes that we con-
sider interesting either because they provide an ideal testing ground for the $\text{CH}$ method
($e^+e^- \rightarrow$ hadrons and the Higgs decay into two gluons) or are particularly relevant for
LHC phenomenology (electroweak vector boson, top quark and Higgs production, Higgs
decay into two photons).

We use the results obtained in the global survey (see section 3) to fix the parameters of
the models. We recall that for the $\text{CH}$ model, in the case of observables without initial-state
hadrons, the preferred value is $\lambda = 1$, while for observables involving initial-state hadrons,
it is $\lambda_h = 0.6$.\footnote{It may be tempting to speculate that the smaller value of $\lambda$ in the hadronic case (and therefore a larger
effective expansion parameter for the series) may be explained by the generally larger number of gluons
involved in these processes, and therefore by an expansion parameter closer to $\alpha_s C_A$ than to $\alpha_s C_F$, but we
will refrain from doing so.}
For each process, we compare the uncertainty intervals obtained from the scale-variation procedure with $r = 2$ and $r = 4$ with the 68% and 95% DoB intervals obtained using $\text{CH}$. When analysing the $\text{CH}$ results, we also consider the behaviour of the posterior density function for the remainder of the series $\Delta_k$ when increasing the perturbative order. We show how, in most cases, the inclusion of further information leads to a progressive narrowing of the distribution and a consequent reduction of the uncertainty.

4.1 Processes without hadrons in the initial state

We first consider three processes without hadrons in the initial state: the total cross section for the production of hadrons in $e^+e^-$ collisions and the decay of a Standard Model Higgs boson into a pair of gluons or a pair of photons.

As discussed in [1], the total cross section for $e^+e^- \rightarrow$ hadrons is an ideal testing case for understanding the behaviour of the $\text{CH}$ model as perturbative coefficients up to order $\alpha^3_s$ are available in the literature. Their numerical values are listed in table 5 in appendix A. In table 3a, we summarise the results of our study, comparing the size of the 68% and 95% DoB intervals obtained with the $\text{CH}$ method with the uncertainty interval of the scale-variation procedure for $r = 2$. A graphical representation of these intervals is shown in figure 5. These results show that 68% DoB intervals from $\text{CH}$ are always larger than scale-variation intervals for $r = 2$ and, especially at higher orders, agree better in size with those obtained using scale-variation with $r = 4$. In figure 6, we plot the full posterior distribution for the remainder of the perturbative expansion, $\Delta_k \equiv \sum_{n=k+1}^{\infty}$, at each order $k$. We highlight the regions that contribute to the 68% and 95% DoB intervals and compare them to the $r = 2$ scale-variation intervals, showing how, in this case, the latter is always contained in the flat part of the Bayesian credibility distribution for $\Delta_k$.

At the LHC, Higgs decay rates constitute one of the most important processes which do not involve initial-state hadrons. Their precise knowledge is crucial for the extraction of the Higgs couplings to the other Standard Model particles. In our study, we consider two Higgs decay channels which present complementary characteristics with respect to our theoretical knowledge and to their phenomenological relevance. The first one is the Higgs decay into two gluons which, despite being not relevant for Higgs phenomenology at the LHC because of the large irreducible background due to QCD jets, is especially well suited as a test case for our Bayesian analysis. Indeed, its perturbative QCD expansion is known up to N$^3$LO, and QCD corrections are quite sizeable. Next we study the decay of a Higgs boson into two photons. In this case, QCD corrections are rather small and its perturbative expansion is only known up to NLO. On the other hand, due to its clean experimental signature, it is of great phenomenological importance and it is indeed one of the channels where signs of new physics beyond the Standard Model are expected to appear. Again, numerical values for the coefficients of the perturbative expansions of these observables are collected in table 5 in appendix A, while the results of our analysis are summarised in tables 3b–3c.

For the $H \rightarrow gg$ process, we plot the uncertainty intervals obtained using the scale-variation and the $\text{CH}$ methods in figure 7. We observe that the size of the 68% DoB intervals obtained with the $\text{CH}$ model is, with the exception of the N$^3$LO band, slightly
Table 3. Results for the analysis of missing higher order uncertainties for benchmark processes without hadrons in the initial state. We quote the perturbative order \( k \) at which the observable is calculated, the central value for the theoretical prediction at that order, the MHOs uncertainty intervals computed using the CH model at 68% DoB and 95% DoB, and the uncertainty interval obtained using the scale variation (SV) procedure with \( r = 2 \).

| \( k \) | \( R_{k} \) | \( \text{CH}_{68\% \text{DoB}} \) | \( \text{CH}_{95\% \text{DoB}} \) | \( SV_{r=2} \) |

| 2     | 9.556          | \( \pm 0.004 \) | \( \pm 0.011 \) | \( +0.001 \) \( -0.003 \) |

(c) MHOUs for Higgs decay into two photons. The perturbative series of the observable at the order \( k \) is defined as \( \Gamma_{k}(H \rightarrow \gamma\gamma) = \sum_{n=0}^{k} \alpha_s^n c_n \).
in figure 8. We notice that also for this observable, the $r = 2$ scale-variation interval is always contained in the central plateau. In addition, we observe a progressive narrowing of distributions with increasing perturbative order.

Finally we consider Higgs decay into two photons. In this case, predictions at NLO are included within the LO uncertainty intervals determined using both the $\bar{\text{CH}}$ and the scale-variation ($r = 2$) methods, as can be seen in figure 9. On the other hand, we notice that the 68% DoB intervals are comparable in size with the intervals obtained from scale variation with $r = 4$. This suggests that theoretical uncertainties of the Higgs decay into two photon process, determined with the scale-variation procedure using $r = 2$, may be underestimated if one attempts to assign them a 68% or larger heuristic CL. The posterior density distributions for this process are shown in figure 10.

4.2 Processes with hadrons in the initial state

We now consider a number of processes with hadrons in the initial state for which theoretical predictions are available at least up to NNLO, namely the production in proton-proton collisions of $Z$ and $W$ bosons, top-antitop pairs, and Higgs. These processes are either considered to be standard candles at hadronic colliders, or are particularly relevant for LHC phenomenology. They provide precision tests of the Standard Model, and a significant discrepancy between their experimental measurement and theoretical predictions might be a hint of new physics at the TeV scale.

The numerical values of the perturbative coefficients together with the values used for the renormalisation and factorisation scales and the strong coupling constant, are collected in table 6 in appendix A. In table 7 in the same appendix, we list the cuts used in the computation of the observables.

In table 4, we summarise the results of our studies comparing, for each process, the size of the uncertainty intervals obtained with the $\bar{\text{CH}}$ method (68% and 95% DoB) to the ones obtained using the scale-variation procedure ($r = 2$) at different perturbative orders.
Figure 6. Posterior distribution for the remainder $\Delta_k$ (blue solid) for the $e^+e^- \to$ hadrons process at the Z pole with the CH model, 68% DoB interval (blue fill), 95% DoB interval (light-blue fill), scale-variation interval with $r = 2$ (red solid).

Figure 7. Size of the MHO uncertainty intervals at LO, NLO, NNLO and N$^3$LO for the $H \to gg$ process with the CH model with $\lambda = 1$, compared to those predicted by scale variation.

As far as weak vector boson production is concerned, a graphical comparison of predictions obtained with the CH and the scale-variation methods is shown in figures 11 and 13. We notice a similar behaviour for $W^+$ and $Z$ production. At LO, the 68% DoB uncertainty intervals obtained with the CH prescription are substantially larger than the intervals ob-
Figure 8. Posterior distribution for the remainder $\Delta_k$ (blue solid) for the $H \rightarrow gg$ process with the CH model, 68\% DoB interval (blue fill), 95\% DoB interval (light-blue fill), scale-variation interval with $r = 2$ (red solid).

Figure 9. Size of the MHO uncertainty intervals at NLO and NNLO for the $H \rightarrow \gamma\gamma$ process with the CH model with $\lambda = 1$, compared to those predicted by scale variation.
Figure 10. Posterior distribution for the remainder $\Delta_k$ (blue solid) for the $H \rightarrow \gamma\gamma$ process with the $\chi$H model, 68% DoB interval (blue fill), 95% DoB interval (light-blue fill), scale-variation interval with $r = 2$ (red solid).

The posterior distributions for $\Delta_k$, shown in figures 12 and 14, show a progressive narrowing with the increase of the perturbative order. For the top-pair production process, the comparison of uncertainty intervals obtained using the $\chi$H and scale-variation methods are shown in figure 15. In this case, the NLO result for the cross section is contained in the LO uncertainty band determined by the 68% DoB interval of the $\chi$H prescription, while this is not the case for the scale-variation interval obtained with $r = 2$. On the other hand, the NNLO central prediction for the cross section is outside the LO intervals computed with either method. $\chi$H intervals with a DoB of 68% are similar in size to the scale-variation intervals with $r = 4$, and scale-variation intervals with $r = 2$ are always smaller than the $\chi$H ones at 68% DoB. The posterior distributions for $\Delta_k$ plotted in figure 16 show the expected narrowing as the perturbative order increases, and that the $r = 2$ scale-variation interval is always contained in the flat part of the distribution.

As a final benchmark process, we consider Higgs production in proton-proton collisions, a process which is characterised by large perturbative corrections. The graphical comparison in figure 17 shows that uncertainty intervals determined by scale variation with $r = 2$ do not give a reliable error estimate for MHOUs for this observable, neither at LO nor at NLO. We observe that the $\chi$H 68% DoB intervals are comparable in size with scale-variation intervals obtained with $r = 4$. They both fail to properly estimate the large NLO correction, the central result at NLO being far outside the LO uncertainty band, and
the error bars at NLO not even overlapping with the LO ones. The CH method appears to produce a more reliable estimation of uncertainty intervals at higher orders, with the 68% DoB intervals at NLO and NNLO showing a substantial overlap. The slowly-converging pattern of the perturbative expansion for the Higgs cross section prediction is reflected in the behaviour of the posterior distributions for $\Delta_k$, which are shown in figure 18. We observe that the narrowing of the posterior distribution with increasing perturbative order is now much less pronounced than for the other observables that we have considered in this section. Also, the flat part of the posterior distribution for Higgs production broadens significantly when going from LO to NLO.

5 Conclusions and outlook

In this paper, we have investigated the performance of two approaches in estimating the theoretical uncertainties due to missing higher orders in perturbative QCD computations. The first one is the widely used prescription of varying the unphysical factorisation and renormalisation scales around a central value. The second (CH) is a modified version of the Bayesian approach introduced by Cacciari and Houdeau in [1].

We have performed a global survey based on a wide set of perturbative observables. Within this set, we have considered two categories, characterised by the absence (“non-hadronic”) or the presence (“hadronic”) of hadrons in the initial state of a process, and we have analysed them separately. The outcome of this survey has allowed us to assign a heuristic confidence level to the uncertainty intervals returned by the scale-variation approach and, in a separate analysis, to determine an optimal expansion parameter to be employed in the CH Bayesian approach.
(a) MHOUs for $W$ production in the Drell-Yan process at $\sqrt{s} = 8$ TeV. The perturbative series of the observable at the order $k$ is defined as $\sigma_k(pp \rightarrow W^+ \rightarrow l^+\nu_l) = \sum_{n=0}^{k} \alpha^s h_n$.

| Order | $\sigma_k$ [nb] | CH$_{68\%$DoB} | CH$_{95\%$DoB} | SV$_{r=2}$ |
|-------|----------------|----------------|----------------|----------|
| $k = 0$ | 3.328 $\pm 1.051$ | $\pm 6.729$ | +0.319 | -0.362 |
| $k = 1$ | 3.718 $\pm 0.139$ | $\pm 0.351$ | +0.095 | -0.147 |
| $k = 2$ | 3.704 $\pm 0.050$ | $\pm 0.094$ | +0.061 | -0.077 |

(b) MHOUs for $Z$ production in the Drell-Yan process at $\sqrt{s} = 8$ TeV. The perturbative series of the observable at the order $k$ is defined as $\sigma_k(pp \rightarrow Z \rightarrow e^+e^-) = \sum_{n=0}^{k} \alpha^s h_n$.

| Order | $\sigma_k$ [nb] | CH$_{68\%$DoB} | CH$_{95\%$DoB} | SV$_{r=2}$ |
|-------|----------------|----------------|----------------|----------|
| $k = 0$ | 0.4995 $\pm 0.1548$ | $\pm 0.9907$ | +0.047 | -0.054 |
| $k = 1$ | 0.5574 $\pm 0.0201$ | $\pm 0.0507$ | +0.012 | -0.020 |
| $k = 2$ | 0.5551 $\pm 0.0071$ | $\pm 0.0133$ | +0.010 | -0.007 |

(c) MHOUs for $t\bar{t}$ production at $\sqrt{s} = 8$ TeV. The perturbative series of the observable at the order $k$ is defined as $\sigma_k(pp \rightarrow t\bar{t}) = \sum_{n=2}^{k} \alpha^s h_n$.

| Order | $\sigma_k$ [pb] | CH$_{68\%$DoB} | CH$_{95\%$DoB} | SV$_{r=2}$ |
|-------|----------------|----------------|----------------|----------|
| $k = 2$ | 146.32 $\pm 82.61$ | $\pm 528.76$ | +51.08 | -34.32 |
| $k = 3$ | 217.38 $\pm 39.32$ | $\pm 99.46$ | +26.94 | -26.89 |
| $k = 4$ | 244.36 $\pm 25.24$ | $\pm 47.60$ | +12.42 | -13.52 |

(d) MHOUs for Higgs production in gluon fusion at $\sqrt{s} = 8$ TeV. The perturbative series of the observable at the order $k$ is defined as $\sigma_k(pp \rightarrow H) = \sum_{n=2}^{k} \alpha^s h_n$.

| Order | $\sigma_k$ [pb] | CH$_{68\%$DoB} | CH$_{95\%$DoB} | SV$_{r=2}$ |

| $k = 2$ | 5.6 $\pm 3.35$ | $\pm 21.46$ | +1.26 | -0.98 |
| $k = 3$ | 13.3 $\pm 4.51$ | $\pm 11.42$ | +2.74 | -2.17 |
| $k = 4$ | 18.37 $\pm 3.52$ | $\pm 6.65$ | +2.00 | -2.06 |

Table 4. Results for the analysis of missing higher order uncertainties for benchmark processes with initial-state hadrons. We quote the perturbative order $k$ at which the observable is calculated, the central value for the theoretical prediction at that order, the MHOs uncertainty intervals computed using the CH model at 68% DoB and 95% DoB, and the uncertainty interval obtained using the scale variation (SV) procedure with $r = 2$. 
Figure 12. Posterior distribution for the remainder $\Delta_k$ (blue solid) for the $pp \rightarrow W^+$ process at $\sqrt{S} = 8$ TeV with the CH model, 68% DoB interval (blue fill), 95% DoB interval (light-blue fill), scale-variation interval (red solid).

Figure 13. Size of the MHO uncertainty intervals at LO, NLO and NNLO for the $pp \rightarrow Z$ process at $\sqrt{S} = 8$ TeV with the CH model with $\lambda_h = 0.6$, compared to those predicted by scale variation.

We have found that, in the scale-variation approach, the standard variation within a factor of two with respect to the central scale can lead to uncertainty intervals whose heuristic confidence level (CL) falls short of a conventional 68%, thereby potentially underestimating the real uncertainty. This is true for both the non-hadronic observables and,
more markedly, for the hadronic ones. We have determined that the rescaling factor needed to obtain 68%-heuristic CL intervals is usually larger than two, with the specific value depending on the class of observables under consideration and on the prescription used. In general, and conservatively, a rescaling factor between three and four appears more likely to give an estimation of the missing higher orders uncertainty that is consistent with a 68%-heuristic CL interpretation of the scale-variation intervals.
Figure 16. Posterior distribution for the remainder $\Delta_k$ (blue solid) for the $pp \rightarrow t\bar{t}$ process at $\sqrt{S} = 8$ TeV with the CH model, 68% DoB interval (blue fill), 95% DoB interval (light-blue fill), scale-variation interval (red solid).

Figure 17. Size of the MHO uncertainty intervals at LO, NLO and NNLO for the $pp \rightarrow H$ via gluon fusion process at $\sqrt{S} = 8$ TeV with the CH model with $\lambda_h = 0.6$, compared to those predicted by scale variation.

Our analysis of the CH approach has allowed us to determine that $\alpha_s$ is an appropriate expansion parameter for non-hadronic observables, while a slightly larger parameter, $\alpha_s/\lambda_h$, with $\lambda_h \approx 0.6$, appears to be more appropriate for hadronic observables.
Armed with the determination of these expansion parameters from the global survey, we have then compared the performances of the scale-variation and the CH Bayesian approaches in the estimation of the MHOUs for a set of benchmark observables of particular interest for LHC physics, namely the production of electroweak vector bosons, top-antitop pairs and Higgs in proton-proton collisions. The two approaches perform similarly in estimating, to a given heuristic confidence level for the scale-variation approach or to a given credibility level for the Bayesian CH approach, the MHOUs for these observables, provided that a rescaling factor larger than two is used for scale variation. More importantly, however, the CH approach additionally provides a full probability density distribution for the missing higher orders uncertainty. This probability density can then be used to combine in a meaningful way the MHOU with uncertainties of different origin, e.g. experimental ones.

We conclude by commenting on two possible avenues for further development. First, in this paper, we have determined the optimal expansion parameter for the perturbative series in the CH approach by performing a frequentist analysis of a set of known observables. One could envisage replacing this analysis with an additional prior on the expansion parameter. Second, the CH model has been formulated as an as generic Bayesian approach as possible, meant to be applied to a wide and open-ended class of perturbative observables. Instead, one could envisage developing other, more refined Bayesian models, crafted to work on a more restricted and more uniform class of observables. In such a case, more specific knowledge about the perturbative behaviour of the observables would be encoded in the priors of the model, and a trade-off would exist between this amount of information and the model’s eventual predictivity. We leave exploration of these avenues to further work.

Figure 18. Posterior distribution for the remainder $\Delta_k$ (blue solid) for the $pp \rightarrow H$ via gluon fusion process at $\sqrt{S} = 8$ TeV with the CH model, 68% DoB interval (blue fill), 95% DoB interval (light-blue fill), scale-variation interval (red solid).

A Numerical values of perturbative coefficients

The observables used in our analyses are listed in table 5 and table 6.

Table 5 gives the perturbative coefficients for non-hadronic observables, i.e. without hadrons in the initial state. They are given in the form

\[ O_k(Q, \mu_r) = \sum_{n=l}^{k} \alpha_s^n(\mu_r) c_n(Q, \mu_r), \]  

(A.1)

where \( \mu_r \) is the renormalisation scale of the strong coupling, which we choose equal to the typical scale of the process, \( Q \), when calculating the coefficients given in the table. We recall that for this class of observables, the coefficients \( c_0 \) are not used in the Bayesian analysis.

Hadronic observables (i.e. with hadrons in the initial state) are written as

\[ O_k(Q, \mu_r, \mu_f) = \sum_{n=l}^{k} \alpha_s^n(\mu_r) h_n(\mu_r, \mu_f) \equiv \sum_{n=l}^{k} \alpha_s^n(\mu_r) \mathcal{L}(\mu_f) \otimes C_n(Q, \mu_r, \mu_f). \]  

(A.2)

We present in table 6, setting \( \mu_r = \mu_f = Q \), the coefficients obtained after convolution with the parton-parton flux, as explained in section 2.3.1. Finally, in table 7, we list the cuts applied in the numerical computations of hadronic observables.

B Hadronic observables: convoluted coefficients vs. dominant Mellin moment method

Our preferred extension of the CH model to hadronic observables is the one based on the convoluted coefficients (see section 2.3.1), due to its ability to capture effectively the full complexity of a process with initial-state hadrons and multiple partonic channels. However, it is instructive to compare its results with those of the Mellin-moment approach described in section 2.3.1. In this appendix, we review two processes: Higgs production in gluon fusion, where, as we will see, the Mellin method and the coefficient one return equivalent results, and the Drell-Yan process, where the Mellin method fails to capture the essence of the process.
Non-Hadronic observables

Table 5. QCD perturbative corrections for observables without initial-state hadrons. The coefficients $c_n$ are defined by $O_k = \sum_{n=1}^{k} \alpha_s^n c_n$, where $O_k$ is an observable computed at $k$th order in perturbative QCD. Notice that $l = 0$ coefficients are not used in the Bayesian non-hadronic analysis.

B.1 Higgs production in gluon fusion at the LHC

This process is characterised by the dominance at every perturbative order of the gluon-gluon channel. The other partonic channels, which only enter at NLO and at NNLO order, turn out to only give subleading contributions. We calculate the dominant moment of the Higgs coefficient functions in Mellin space given in [41] using a saddle-point approximation [15, 16]. We find that $N_0 = 2$ gives the best approximation of the full Mellin inversion integral. We then compare the MHOUs obtained following this procedure with those from the convoluted coefficients method in table 8a. We see that the behaviour of the dominant Mellin moments at the various perturbative orders is very similar to the one of the coefficients extracted after the convolution with the PDFs. Indeed, as shown also in figure 19, the resulting uncertainty intervals in the two approaches agree very well.

B.2 The Drell-Yan process at the LHC

The Drell-Yan process for $Z$ production at the LHC is dominated by the $q\bar{q}$ channel both at LO (where it is the only channel) and at NLO, where also the quark-gluon channel starts to contribute. At NNLO, also the gluon-gluon channel opens up. It is known that the total

Table 6. QCD perturbative corrections for observables with initial-state hadrons. The coefficients $h_n$ are defined by $O_k = \sum_{n=0}^{k} \alpha_s^n h_n = \sum_{n=0}^{k} \alpha_s^n C \otimes C_n$, where $O_k$ is an observable computed at $k^{th}$ order in perturbative QCD. All observables have been computed for the LHC (proton-proton collisions at $\sqrt{S} = 8$ TeV) with the cuts given in table 7.

The net effect of the new channels on the total NNLO contribution is PDF-dependent, due to the uncertainties of the gluon PDFs. In particular, the NNLO contribution can change sign according to the PDF set used.

In our case, using the NNLO NNPDF 2.3 set [37], it is negative due to the predominance of the negative quark-gluon channel at this order. On the other hand, the Mellin-space coefficient function for the $q\bar{q}$ channel, which we use in the analysis, is always positive. Hence, it is not able to capture the complex pattern of the perturbative expansion for this process. Indeed, we see in table 8b and in figure 20 that, starting from NLO, the uncertainty interval obtained with the Mellin method is systematically larger than the one obtained with the standard coefficient-based one.

One could in principle work around this issue by performing a Mellin analysis for each channel separately. However, to recombine the different uncertainties in order to get a single band for the complete cross section would then require the knowledge of the weight of each channel. This, in turn, requires the use of the PDFs to determine the corresponding parton fluxes, introducing a dependence on long-range physics into the Mellin moment method, and therefore spoiling its main advantage.
Hadronic analysis cuts

| Cut Description                                                                 |

(b) MHOUs for $Z$ production in the Drell-Yan process. The perturbative series of the observable at the order $k$ is defined as $\sigma_k(pp \rightarrow Z \rightarrow e^+e^-) = \sum_{n=0}^{k} \alpha_s^n h_n$.

Table 8. Results for the analysis of Higgs production in proton-proton collisions and of Drell-Yan production of a $Z$ boson at $\sqrt{s} = 8$ TeV. We quote the perturbative order $k$ at which the observable is calculated, the central value for the theoretical prediction at that order, the value of the coefficient function at the dominant Mellin moment $N_0$ and the MHOs uncertainty intervals computed using the CH model at 68% DoB and 95% DoB with both the Mellin moment method and the coefficient-based approach.
Figure 19. Size of the MHO uncertainty intervals at LO, NLO and NNLO for the $pp \rightarrow H$ via gluon fusion process at $\sqrt{S} = 8$ TeV. Predictions of the Mellin-$\widetilde{\text{CH}}$ model with $\lambda_h = 0.6$, compared to those of the standard $\widetilde{\text{CH}}$ method and of the scale-variation approach.

Figure 20. Size of the MHO uncertainty intervals at LO, NLO and NNLO for the $pp \rightarrow Z$ process at $\sqrt{S} = 8$ TeV. Predictions of the Mellin-$\widetilde{\text{CH}}$ model with $\lambda_h = 0.6$, compared to those of the standard $\widetilde{\text{CH}}$ method and of the scale-variation approach.

C Statistical uncertainty in the determination of $\lambda$

In this appendix, we detail the procedure through which we determine the uncertainty on our determination of the rescaling factor $\lambda (\lambda_h)$ of the expansion parameter in the $\widetilde{\text{CH}}$ approach. We recall that the optimal value for $\lambda$ is determined by comparing, for the $\widetilde{\text{CH}}$ model with a given value of $\lambda$, the measured success rate and the value of the Degree of Belief given as an input. The success rate is defined as the ratio of the number of higher order results included in the predicted uncertainty intervals and the total number of observables analysed.
What we need to establish is the statistical uncertainty on the measured success rate, resulting from the finite size of the sample of observables that we employ in our survey. For this purpose, we follow the procedure suggested in [42]. It relies on the assumption that the measured success rate, \( s/n \), where \( s \) is the number of successes and \( n \) the size of the observables’ sample, is a point estimator for \( p \), the real proportion of successes in the underlying population. The likelihood of observing a success rate value \( s/n \), given the true value \( p \), is then proportional to \( p^s(1-p)^{n-s} \), and upon normalisation over the interval \( 0 < p < 1 \), it can be written as a Beta distribution,

\[
B(s + 1, n - s + 1) = \frac{(n + 1)!}{s!(n - s)!} p^s(1-p)^{n-s}.
\]  

(C.1)

If we express our ignorance on the value of \( p \) by means of a Bayes-Laplace uniform prior, \( P_{pr}(p) = 1 \) over the interval \( 0 < p < 1 \), we can, upon application of Bayes’ theorem, use the normalised likelihood function (C.1) as a posterior probability distribution. We can then define the lower and upper bounds, \( p_l \) and \( p_u \), of an equal-tailed \( c \% = 1 - \alpha \) credibility interval for \( p \) through the relations

\[
\int_0^{p_l} dp B(s + 1, n - s + 1) = \frac{\alpha}{2} \quad \text{and} \quad \int_{p_u}^1 dp B(s + 1, n - s + 1) = \frac{\alpha}{2},
\]  

(C.2)

respectively.

A proper application of this procedure to our problem would require the evaluation, for each value of \( \lambda \) and for each measured \( s/n \) rate, of the credibility interval \([p_l, p_u]\) for a given value of \( \alpha \). In practice, in order to simplify both the calculation and the graphical representation of this uncertainty, we determine a 68.3%-credible interval for an ideal curve where success rate = requested DoB. This is the interval that is represented as a grey band in the right hand plots of figures 3 and 4. As long as the actual curves do not differ too much from this ideal one, one can easily gauge the size of the uncertainty, and therefore to what extent two curves obtained with two values of \( \lambda \) are, or are not, significantly different.
