Abstract (J Korean Assoc Oral Maxillofac Surg 2017;43 Suppl 1:S9-13)

Accidental displacement of the third molar tooth or its fragment into the anatomical spaces is a rare but potentially serious complication. The most common sites of mandibular third molar displacement are the sublingual, submandibular, and pterygomandibular spaces. Removal of a displaced tooth or its fragments from these spaces may be difficult due to poor access and the vital structures involved in these spaces; therefore, removal may result in permanent damage. This article is intended to provide a concise update of the reported cases of submandibular displacement and to present a case of intraoral management of mandibular third molar root fragments that were displaced into the submandibular space.

Key words: Tooth extraction, Third molar, Displacement, Paresthesia

[paper submitted 2017. 2. 17 / revised 2017. 4. 13 / accepted 2017. 5. 7]

I. Introduction

Removal of the third molar remains one of the most common oral and maxillofacial surgical procedure and is associated with low morbidity¹⁻⁵. However, like all surgeries, surgical removal of the third molar may be associated with several complications. These complications are more common in the mandible than in the maxilla, with reported incidences ranging from 2.6% to 30.9%⁶⁻¹¹. Accidental displacement of the third molar tooth or root fragment into into different facial spaces, including the maxillary sinus¹⁵, infratemporal⁵⁻¹⁰, pterygomandibular⁶⁻¹⁴, lateral pharyngeal¹⁵⁻¹⁷, lateral cervical¹⁸, pterygopalatine¹⁹, buccal²⁰, sublingual²¹, and submandibular spaces. The maxillary sinus and submandibular spaces are the two most commonly affected. Since so few cases have been published, no consensus has yet been reached in terms of the optimum management protocol that can be applied in all circumstances²²⁻²³.

Here, we present a case of displacement into the submandibular space and review related published cases. To this end, the PubMed-MEDLINE and Google Scholar databases were searched for papers about iatrogenic displacement of the mandibular third molar tooth or tooth fragment into the submandibular space. The date range extended through 2017. The search was performed using the keywords ‘displacement’, ‘submandibular space’, ‘mandibular third molar’, ‘accidental’, ‘complication’, and combinations thereof.

II. Case Report

A 48-year-old female patient was referred to Oral and Maxillofacial Surgery Clinic with complaints of headache, paresthesia on the right lateral region of the tongue, and taste impairment. She had undergone a mandibular third molar extraction performed by a general practitioner 3 months earlier.

CASE REPORT
Panoramic radiography showed the presence of a radiopaque mass similar to that of a tooth root. (Fig. 1) Cone-beam computed tomography (CBCT) scans were obtained for detailed radiographic examination and revealed high density areas in the submandibular region. (Fig. 2) A surgical operation was planned under general anesthesia. Potential complications were explained to the patient and written consent was obtained.

Under general anesthesia, a conventional lingual flap starting from the disto-lingual angle of the first molar was extended to the anterior surface of ramus. The flap was reflected up to the submandibular region with great care and support from an extra-orally placed finger. (Fig. 3). The dislodged root fragments were found by blunt dissection, grasped with a pair of forceps, and removed. (Fig. 4) The patient was given oral antibiotics and analgesics. One week after surgery, the healing of soft tissue was uneventful. However, the patient’s complaints of numbness, intense pain, burning tongue, and taste impairment were still present and altered her daily life significantly after the operation.

III. Discussion

Accidental displacement of the mandibular third molar tooth or fragments into the submandibular space is very rare, with a reported incidence of less than 1%.2 The first case of iatrogenic submandibular displacement was reported by Ho24 in 1980; to date, only 12 reports have been pub-
The submandibular space is a complex triangular compartment that is bounded superiorly by the mylohyoid muscle, anteriorly by the medial surface of the mandible and the skin, and inferiorly by the superficial fascia and platysma muscle. It encloses vital anatomic structures such as the submandibular salivary gland, facial artery/vein, lingual nerve, and hypoglossal nerve. The submandibular space also freely communicates superiorly with the sublingual space and inferiorly with the lateral pharyngeal space. Therefore, accidental displacement of a mandibular third molar root or fragments into this space poses a risk of iatrogenic injury to vital structures. Moreover, the root or fragments could potentially be displaced further into deeper facial spaces. Such deeper displacements usually require additional invasive approaches.

A displaced tooth may remain asymptomatic or cause pain, swelling, paresthesia, and trismus. The effects of a displaced tooth depend on its size, location, and whether or not there is an infection. Solanki et al. reported a case of mandibular third molar displacement into the submandibular space that remained asymptomatic for two years. In a case reported by Anand and Patil, dysesthesia occurred immediately in the lip after an unsuccessful surgery performed by a general practitioner. Aznar-Arasa et al. reported 6 cases of sublingual displacement; five of the six patients remained asymptomatic. According to Aznar-Arasa et al., the symptoms are closely related to the size of the displaced fragment and displacement tends to trigger symptoms when the size of the fragment exceeds 5 mm. In the present case, both medial and distal root fragments of the third molar tooth exceeding 5 mm were displaced into the submandibular fossa and caused paresthesia on the right lateral region of the tongue after the first surgery. Due to the severe psychological distress of the patient, the case management was dramatically complicated.

Once the complication occurs, it is important to rigorously evaluate the severity of the condition. Any attempt to retrieve the displaced tooth or fragment without adequate visuality and surgical/anatomical knowledge may result in further displacement into deeper facial spaces, iatrogenic injury to the vital structures, and life-threatening events such as deep neck infection, mediastinites, and airway compromise. Based on the reported cases, it can be concluded that the majority of cases resolved with minimal complications. However, early intervention and proper management are essential to prevent potential adverse outcomes.
Iatrogenic displacements were caused by practitioners with a lack of surgical expertise. Adeyemi et al. reported a case of submassesteric abscess that occurred 1 month after submandibular displacement. The present case showed persistent dysaesthesia caused by an unsuccessful first surgical attempt by a practitioner. Moreover, the operator may be faced with legal implications related to this unsuccessful surgery. Thus, it is prudent to stop the operation, inform the patient about the condition, and refer the patient to a maxillofacial surgeon as soon as possible.

On the other hand, this complication can occasionally occur even in the hands of the most experienced surgeons. Grandini et al. reported a case in which a dental surgeon caused the mandibular third molar to displace into the submandibular space and failed to retrieve the tooth for 6 hours, leading to severe tissue injury. Thus, in addition to surgical knowledge and experience, adequate pre-surgical planning, clinical and radiographic examinations, adequate access and visibility, proper technique, and controlled use of force are crucial for reducing the incidence and legal problems of this complication.

Advanced imaging techniques are useful for thorough case evaluation when complications occur. Computed tomography is considered the most suitable technique and enables the exact location and size of the displaced tooth or tooth fragment to be pinpointed. However, CBCT scanning, which has the advantage of low radiation exposure, can be used preferably if the fragment or tooth is displaced into deep spaces. Panoramic, postero-anterior, submento-vertex, and occlusal views, in addition to image intensifiers, are among the other imaging modalities that can also be used to determine the location of displaced teeth or fragments. We used CBCT to evaluate the fragment locations and sizes because this technique is already available in our Oral and Maxillofacial Surgery Clinic.

No clear consensus has been reached regarding the retrieval time of displaced teeth or their fragments. Some authors have suggested delaying tooth or fragment retrieval to allow fibrosis to develop, but others have claimed that delaying fragment removal can result in severe pain, infection, and further migration of the root or root fragment into deep facial spaces. These authors suggest removal of the tooth or fragment as soon as possible. We conclude that if the fragment is small, is not accompanied by any symptoms, and is in a deep position, then it is better to keep the fragment under observation to prevent further tissue injuries. However, if the patient has symptoms associated with the displaced tooth or fragment and also has severe psychological distress, as in the present case, surgical removal of the fragment should be performed after explaining all possible complications to the patient.

Access to the submandibular space is difficult because of the anatomical structures enclosed by this space. Many surgical approaches, including trans-oral approaches via general or local anesthesia and extra-oral approaches via local or general anesthesia, have been reported. In 2002, Yeh reported a modified technique using a combination of intraoral and extraoral approaches to facilitate the retrieval of displaced teeth and fragments. In addition to the conventional lingual flap extended to the first molar, a hemostat was inserted to stabilize the fragment via a skin incision that was made in the submandibular region. Moreover, recent advancements in biotechnology computer-assisted navigation systems have enabled retrieval of displaced teeth in a matter of minutes. In the present case, adequate access and visualization were achieved with a preoperative CBCT scan and by carefully reflecting a deep lingual flap up to the submandibular region and supporting the flap extra-orally with digital pressure.

In conclusion, trans-operative displacement of a tooth or tooth fragment into the facial spaces is a rare but potentially serious condition, commonly requiring a second surgery. A second major procedure may cause further complications or worsen existing ones, as in our case. Thus, the best way to manage a surgical complication is prevention. This can be achieved by thorough evaluation of all significant risk factors and careful execution of the surgical procedure. Also, for optimal surgical outcomes, operation should be preferably performed by maxillofacial surgeons who are highly familiarized with the surgical morphology of the head and neck.
