We consider a many-body system of pseudo-spin-1/2 bosons with spin-orbit interactions, which couple the momentum and the internal pseudo-spin degree of freedom created by spatially varying laser fields. The corresponding single-particle spectrum is generally anisotropic and contains two degenerate minima at finite momenta. At low temperatures, the many-body system condenses into these minima generating a new type of entangled Bose-Einstein condensate. We show that in the presence of weak density-density interactions the many-body ground state is characterized by a twofold degeneracy. The corresponding many-body wave function describes a condensate of “left-” and “right-moving” bosons. By fine-tuning the parameters of the laser field, one can obtain a bosonic version of the spin-orbit coupled Rashba model. In this symmetric case, the degeneracy of the ground state is very large, which may lead to phases with nontrivial topological properties. We argue that the predicted new type of Bose-Einstein condensates can be observed experimentally via time-of-flight imaging, which will show characteristic multiplet structures in momentum distribution.

I. INTRODUCTION

Bose-Einstein condensation is an old and thoroughly studied quantum phenomenon, where a many-body system of bosons undergoes a phase transition in which a single-particle state becomes macroscopically occupied. This phenomenon has been observed in condensed matter systems and more recently in experiments on cold atomic gases, which provided a unique avenue to visualize the formation of the Bose-Einstein condensate (BEC). Bose-Einstein condensation is a phase transition driven mostly by the statistics of the underlying bosonic excitations and not by interactions. The statistics of basic particles are determined by the particle spin via the fundamental Pauli spin-statistics theorem. The spin must be integer for bosons and half-integer for fermions.

In this paper, we discuss a cold atomic system of multilevel bosons moving in the presence of spatially-varying laser fields, which give rise to an emergent pseudo-spin-1/2 degree of freedom for the bosons. We emphasize from the outset that the symmetry operations in the pseudo-spin space are not related to real-space rotations and thus there is no contradiction between the existence of the pseudo-spin-1/2 bosons and the fundamental Pauli theorem. To "create" the pseudo-spin-1/2 bosons, one can use the experimental setup, proposed in Refs. 4, 5, 6, 7, 8, 9, in which three degenerate hyperfine ground states |1⟩, |2⟩, |3⟩ are coupled to an excited state |0⟩ by spatially varying laser fields. This "tripod scheme" leads to the appearance of a pair of degenerate dark states, spanning a subspace which is well separated in energy from two nondegenerate bright states. The coupling between the dark and the bright states is very weak and will be neglected (adiabatic approximation). The parameter which labels the dark states plays the role of a pseudo-spin index. This emergent pseudo-spin degree of freedom is similar to that studied recently in the context of spinor condensates. In particular, various aspects of the pseudo spin-1/2 boson physics were addressed using two hyperfine states to support the internal degree of freedom associated with the pseudo spin. The key distinctive feature of the systems studied in this paper is that the single-particle Hamiltonian projected onto the subspace of the degenerate dark states generally possesses a non-Abelian gauge structure. I.e., the kinetic term of the effective Hamiltonian has the form $\hat{H}_{\text{kin}} = (\mathbf{p} - \hat{A})^2 / 2m$, where $\hat{A}(\mathbf{r})$ is a matrix in the pseudo-spin space. In a recent Letter, we pointed out that under certain conditions this non-Abelian gauge structure is equivalent to a spin-orbit interaction. To understand the nature of this interaction, we note that the dark states are eigenstates of an atom at rest. Once the atom moves in the spatially modulated laser field, the dark state label, i.e., the pseudo-spin index, is not a good quantum number and the pseudo-spin starts to precess about the direction of the momentum. This coupling between the internal degree of freedom associated with the dark state subspace and the orbital movement of the particle represents the spin-orbit interaction.

The article is organized as follows: In Section II we introduce our model and discuss the properties of a noninteracting many-body system of bosons with spin-orbit interactions. We find that, in general, the single-particle spectrum is characterized by two degenerate minima at finite momenta and we determine the transition temperature for the bosons condensing into these minima. In

arXiv:0712.2256v3 [cond-mat.other] 31 Aug 2008
underlying laser-atom Hamiltonian is cited state |. The corresponding many-body wavefunction describes a NOON state, suggesting that future studies of the SOBEC state in the context of quantum entanglement and quantum interference are highly relevant. For completeness, we also derive the Gross-Pitaevskii equations for the spin-orbit coupled condensate (Subsection III B). Linearizing the coupled non-linear equations in the vicinity of a stationary solution leads to a spectrum of excitations that reproduces the generalized Bogoliubov result. A possible experimental signature of the new type of SOBEC is described in Section IV. We argue that a SOBEC can be observed via time-of-flight imaging, which will show a characteristic multi-peak structure of the density profiles. We demonstrate that such a measurement generates distinct outputs for "left-" and "right-moving" condensates and thus can be viewed as a measurement of a qubit. A summary of the paper along with our conclusions are presented in Section V.

II. SPIN-ORBIT INTERACTING HAMILTONIAN AND SINGLE-PARTICLE SPECTRUM

We start with the following many-body Hamiltonian describing spin-orbit coupled bosons,

\[ \hat{H} = \sum_{p,\alpha,\beta} \frac{p^2}{2m} \left\{ \hat{P}_p \hat{\sigma}_2 - v_p \hat{P}_p \hat{\sigma}_3 \right\} \alpha \beta \hat{a}_{\alpha \beta, p}, \]  

(1)

where \( \hat{a}_{\alpha \beta, p} \) and \( \hat{a}_{\alpha \beta, p}^\dagger \) are the creation and annihilation operators for bosons in the state with momentum \( p \) and pseudo-spin \( \alpha = \uparrow, \downarrow \), \( \hat{\sigma}_i \) are the Pauli matrices in the pseudo-spin space, and the parameters \( v \) and \( v' \) characterize the strength and anisotropy of the spin-orbit coupling. We reiterate that this type of spin-orbit-coupled Hamiltonian will appear within the recently proposed tripod scheme \[15,6,7,8,9,10\] in which three hyperfine ground states of an atom |1\rangle, |2\rangle, and |3\rangle are coupled to an excited state |0\rangle via spatially modulated laser fields. The underlying laser-atom Hamiltonian is

\[ \mathcal{H}_{a-1} = \Omega_0 \langle 0 | - v_p \hat{P}_p \hat{\sigma}_3 | 0 \rangle \langle \mu | + \text{h. c.}, \]  

(2)

where \( \Omega_0 \) is a constant detuning to the excited state and the Rabi frequencies consistent with the realization of an effective spin-orbit interaction can be taken as \( \Omega_1 (r) = \Omega \sin \theta \cos (mv_a x)e^{i m v_y y}, \Omega_2 (r) = \Omega \sin \theta \sin (mv_a x)e^{i m v_y y}, \) and \( \Omega_3 (r) = \Omega \cos \theta, \) with \( \Omega, \theta, \) \( v_a \) and \( v_b \) being constants (see, e.g., Refs. 6 and 10 for details). Diagonalizing the atom-laser Hamiltonian via a position-dependent rotation \( R_{\alpha \beta} (r) \), with \( \alpha \in \{ \uparrow, \downarrow \}, \beta \in \{ 1, 2 \} \) and \( \mu \in \{ 0, 1, 2 \} \), generates a pair of degenerate dark states

\[ |1\rangle = \sin \Phi_x e^{i S_y} |1\rangle - \cos \Phi_x e^{-i S_y} |2\rangle, \]  

(3)

\[ |\downarrow\rangle = \cos \theta \sin \Phi_x e^{i S_y} |1\rangle + \cos \theta \sin \Phi_x e^{-i S_y} |2\rangle - \sin \theta |3\rangle, \]

with \( \Phi_x = m v_a x \) and \( S_y = m v_b y \), and two non-degenerate bright states \( |b_{1,2}\rangle \). The pseudo-spin-1/2 structure emerges when the problem is projected onto the subspace spanned by the pair of degenerate dark states.\[22\] Applying the position-dependent rotation \( R_{\alpha \beta} (r) \) to the kinetic energy term in the Hamiltonian generates a coupling of the pseudo-spin to momentum [see Eq. (1)] with \( v = v_a \cos \theta \) and \( v' = v_b \sin \theta \). In the given parametrization. These coupling constants can be easily adjusted by changing the parameters \( v_a, v_b \) and \( \theta \) of the laser fields, which provides a knob to tune the strength and form of the spin-orbit interaction.

Now, we concentrate on the generic case characterized by anisotropic spin-orbit interactions and assume for concreteness that \( v > v' > 0 \). The trap potential and the inter-particle interaction are initially disregarded and discussed in the following sections. The single-particle spectrum of Hamiltonian (1) is (see Fig. 1):

\[ E_\lambda (p) = \frac{p^2}{2m} + \lambda \sqrt{v^2 p_x^2 + v'^2 p_y^2}, \]  

(4)

where \( \lambda = \pm 1 \) labels the bands. The corresponding eigenfunctions \( \phi_{\lambda \alpha} (r) = e^{i P \cdot r} U_\lambda (\alpha, p) \) are spinors with compo-
where \( \chi_p \) is the azimuthal angle in the \((p_x, p_y)\)-plane and \( \Delta = v'/v < 1 \). The unitary matrix \( U_{\lambda}(\chi_p) \) diagonalizes the Hamiltonian (11) (where \( \alpha = \uparrow, \downarrow \) corresponds to the pseudo-spin index and \( \lambda = \pm 1 \) labels the eigenstates).

It is obvious from Eq. (11) that the spectrum of the single-particle problem contains two minima at \( \lambda = -1 \) and momenta \( p_y = p_z = 0 \) and \( p_x = \pm mv \neq 0 \) (see Fig. 1). Consequently, the single particle ground-state is double-degenerate and the most general expression for the corresponding wave-function is

\[
\Psi_{dw}(r) = \sqrt{w_L}(1 - i) e^{-imvz + i\phi_L} + \sqrt{w_R}(1 - i) e^{imvz + i\phi_R},
\]

where \( w_L \geq 0 \) and \( w_R \geq 0 \) are the fractions of “left-” and “right-moving” states subjected to the constraint \( w_L + w_R = 1 \), while \( \phi_L \) and \( \phi_R \) are arbitrary phases. Note that by left/right-moving states we mean states with non-zero momentum average, \( \langle p \rangle = \pm mv e_x \). However, the corresponding average velocity vanishes \( \langle \nabla_p H(p) \rangle = 0 \), so that quasiparticles characterized by these non-zero momentum single-particle states are not actually “moving”, as long as the laser fields generating the spin-orbit coupling are maintained. Note that rotations in the manifold of the double-well ground-states are distinct from rotations in the pseudo-spin Hilbert space, as real-space and pseudo-spin coordinates are mixed up by the spin-orbit interaction. The two-fold degeneracy of the single-particle ground state is preserved if the system is placed in a harmonic trap. For a potential \( V_{trap} = mw_p^2z^2/2 \), we can write the Schrödinger equation in momentum representation: The trap potential plays the role of “the kinetic energy” and the real kinetic term produces a double-well potential in momentum space, see Fig. 1. The tunnelling processes connect the degenerate vacua in momentum space. However, they do not eliminate the double-degeneracy of the single-particle states, which is protected by the Kramers-like symmetry (see Section III.B).

At low temperatures, the many-body Bose system (11) condenses into the single-particle states corresponding to the double-well minima. The transition temperature of this double-well SOBEC can be calculated using standard text-book procedures (22). Let us assume that near and below the transition the band with \( \lambda = 1 \) does not contribute and that we can expand the spectrum near the minima of the band (11). We define the momentum \( q \) in the vicinity of the left/right minima as follows: \( p = \pm mv e_x + q \), with \( q \ll mv \). Eq. (11) leads to the anisotropic spectrum:

\[
\delta E(q) = \frac{q_x^2 + q_y^2}{2m} + \left[ 1 - \left( \frac{v'}{v} \right)^2 \right] \frac{q_z^2}{2m}.
\]

The transition temperature is

\[
T_c = \frac{\pi}{2} \left[ \frac{4}{\zeta(3/2)} \right]^{1/2} \left[ 1 - \left( \frac{v'}{v} \right)^2 \right]^{1/2} \frac{n^{3/2}}{m}.
\]

We see that if \( n^{1/3} \left[ 1 - \left( v'/v \right)^2 \right]^{1/6} \ll mv \), our approximation is justified and, in particular, the density of particles in the upper band \( \lambda = +1 \) is exponentially small.

In the isotropic limit \( \Delta = v'/v \rightarrow 1 \), the transition temperature formally vanishes. Note that in the isotropic case \( v = v' \) the spin-orbit term of the Hamiltonian (11) is equivalent to the Rashba model (23) and can be reduced to the latter via the rotation exp \((i\pi/4)\) in the pseudospin space. In this case, the spectrum (11) has minima on a one-dimensional circle \( \sqrt{p_x^2 + p_y^2} = mv \) (see Fig. 2).

The single-particle ground-state is infinitely degenerate and the most general expression for the corresponding wave-function is

\[
\Psi_{ring}(r) = \int_0^{2\pi} \frac{d\chi}{2\pi} \sqrt{w(\chi)} U_{-\chi}(\chi) e^{i\phi(\chi)} e^{-i[mv(z \cos \chi + y \sin \chi)]},
\]

where \( w(\chi) > 0 \) is the angle-dependent weight of the Bose-condensate on a circle \( \int d\chi/(2\pi)^2 w(\chi) = 1 \) and \( \phi(\chi) \) is the angle-dependent phase. An especially interesting class of ground states corresponds to \( w(\chi) \) not...
vanishing anywhere on the circle. In this case, the phase \( \phi(\chi) \) must satisfy the constraint \( \phi(+2\pi) - \phi(\chi) = 2\pi n \), with \( n \in \mathbb{Z} = \pi \lambda(S_1) \) being an integer winding number. Therefore, there may exist a number of topologically distinct ground states (characterized by the winding number), which can not be deformed into one another via any continuous transformation. We note here that a transition into the ring SOBEC is similar to a “weak-crustallization transition” discussed by Brazovsky (see also, Refs. [29]). In this case, the phase volume of fluctuations is very large, which drives the (classical) transition first order. Even though the transition temperature into the ring SOBEC vanishes in the thermodynamic limit, in a finite trapped system, the energy scale for the crossover into this state will be non-zero [29].

### III. EFFECTS OF DENSITY-DENSITY INTERACTION

The most general ground-state many-body wavefunction of a non-interacting “double well BEC” is

\[
||\Psi_N|| = \sum_{n=0}^{N} c_n \sqrt{n!(N-n)!} \left( \hat{B}_L \right)^n \left( \hat{B}_R \right)^{N-n} ||\text{vac}||, \tag{11}
\]

where \( n \) and \( N \) are the numbers of “left-” and “right-movers,” \( \hat{B}_{L/R} \) are the corresponding creation operators, and \( c_n \) are arbitrary coefficients satisfying \( \sum_n |c_n|^2 = 1 \). In the absence of spin-orbit interaction, a two-component bosonic system has a ferromagnetic ground-state with fully polarized pseudo-spin [12,20]. We emphasize that this is not the case for the double-well many-body ground-state [11] that describes the spin-orbit interacting BEC. All the arguments used for proving the ferromagnetic nature of the ground-state for a two-component system [12] are now irrelevant, as the real-space and spin components of the wave-function cannot be factorized due to the spin-orbit coupling. The non-interacting ground-state [11] has an \((N+1)\)-fold degeneracy. We show below that this large degeneracy is partially lifted by interactions and reduced to a two-fold degeneracy. We assume a density-density interaction \( \mathcal{H}_{\text{int}} = \frac{1}{2} \int d^3r d^3r' \hat{n}(r) \hat{n}(r') V_{\text{int}}(r-r') \hat{n}(r') \), where \( \hat{n}(r) = \sum_{\mu} \hat{\psi}_{\mu}^\dagger(r) \hat{\psi}_{\mu}(r) \) and \( \hat{\psi}_{\mu}(r) \) is the field operator, which is initially defined in terms of the creation/annihilation operators for the original hyperfine states. First, we perform the position-dependent rotation \( R_{\mu\alpha}(r) \) to obtain the effective interaction term, which has the standard form

\[
\mathcal{H}_{\text{int}} = \frac{1}{2V} \sum_{\mathbf{p},\mathbf{p}',\mathbf{q}} V_{\text{int}}(\mathbf{q}) b_{\alpha\mathbf{p}}^\dagger b_{\alpha\mathbf{p} + \mathbf{q}} b_{\beta\mathbf{p}' - \mathbf{q}} b_{\beta\mathbf{p}'}^\dagger, \tag{12}
\]

where \( b_{\alpha\mathbf{p}}^\dagger \) is the creation operator for a state with momentum \( \mathbf{p} \) and pseudo-spin \( \alpha \) in the dark state subspace. We need to perform a second momentum-dependent transformation defined by [5] and [6], which introduces new bosonic operators labelled by the band index \( \lambda = \pm 1 \) (11): \( \hat{B}_{\lambda\mathbf{p}} = U_{\lambda\mathbf{p}}^\dagger (\mathbf{p}) \hat{b}_{\alpha\mathbf{p}} b_{\alpha\mathbf{p}}^\dagger \), and \( \hat{B}_{\lambda\mathbf{p}}^\dagger = \hat{b}_{\lambda\mathbf{p}} b_{\lambda\mathbf{p}}^\dagger U_{\lambda\mathbf{p}}(\mathbf{p}) \), where \( U_{\lambda\mathbf{p}}(\mathbf{p}) = U_{\lambda\mathbf{p}}(\chi) \), and the summation over the spin index \( \alpha \) is implied. In the limit of relatively weak interactions, \( V_{\text{int}} \ll mv^2/2 \) (we emphasize that the spin-orbit coupling strength can be tuned to be arbitrarily strong by adjusting the properties of laser fields), the upper band with \( \lambda = +1 \) is irrelevant for the low-energy physics. Thus, it is convenient to express the Hamiltonian in terms of left/right-moving operators, defined as \( \hat{B}_{\lambda\mathbf{p}} = \hat{B}_{\lambda\mathbf{p}}(\mathbf{q}) = U_{\lambda\mathbf{p}}(\chi + m\mathbf{v}) \). Correspondingly, we have \( U_{\lambda\mathbf{p}}(\mathbf{q}) = U_{\lambda\mathbf{p}}(\chi + m\mathbf{v}) \). This leads to the following interaction Hamiltonian

\[
\hat{H}_{\text{int}} = \frac{1}{2V} \sum_{\mathbf{p},\mathbf{p}',\mathbf{q}} \sum_{\sigma} V_{\text{int}}(\mathbf{q}) b_{\sigma\mathbf{p}}^\dagger b_{\sigma\mathbf{p} + \mathbf{q}} b_{\sigma\mathbf{p}' - \mathbf{q}} b_{\sigma\mathbf{p}'}^\dagger \times U_{\sigma\chi}(\mathbf{p}) U_{\sigma\chi}(\mathbf{q}) U_{\sigma\chi}(\mathbf{p}') U_{\sigma\chi}(\mathbf{q}') - \mathbf{q}. \tag{13}
\]

where the prime sign in the sum over the left and right indices \( \sigma \) is restricted by the condition \( \sigma_1 + \sigma_3 = \sigma_2 + \sigma_4 \), i.e., the numbers of left- and right-movers are conserved, and \( \mathbf{q}_\sigma = \mathbf{q} - (\sigma_1 - \sigma_2)m\mathbf{v} \). We stress that equation (13) is valid in the limit of weak interactions (relative to the spin-orbit coupling) and low temperatures, when only single particle states with momenta in the vicinity of the two minima are occupied.

#### A. Generalized Bogoliubov transformation

Next, we introduce the projection operators \( \hat{P}_{N,n} = \hat{P}_{N,n}^2 \) that select the subspace characterized by \( n \) left-moving and \((N-n)\) right-moving quasiparticles. The Hamiltonian can be expressed as \( \hat{H} = \sum_{n=0}^{N} \hat{P}_{N,n} \hat{H} \hat{P}_{N,n} = \sum_{n=0}^{N} \hat{H}_n \). An important observation is that the Hamiltonian containing the interaction term \( \hat{H}_{\text{int}} \) preserves the number of left- and right-movers and thus we can consider different “sectors,” \( \hat{H}_n \), independently. Our goal is to diagonalize each term \( \hat{H}_n \) using a mean-field scheme and reduce the many-body Hamiltonian to the form

\[
\hat{H} = \sum_{n=0}^{N} \hat{P}_{N,n} \left[ \hat{\mathcal{E}}_0(n) + \sum_{\mathbf{q},\sigma} \Omega_\sigma(n,\mathbf{q}) \hat{\beta}_{n,\sigma}^\dagger \hat{\beta}_{n,\sigma} \right] \hat{P}_{N,n}, \tag{14}
\]

where \( \hat{\mathcal{E}}_0(n) \) is the contribution of the \((n, N-n)\) sector to the condensate energy, while \( \Omega_\sigma(n,\mathbf{q}) \) represents the spectrum of quasi-particle excitations. To obtain the mean-field result, we use a Bogoliubov-type approximation in which the operators corresponding to \( \mathbf{q} = 0 \) are replaced within each sector \((n, N-n)\) by c-numbers, \( \hat{B}_{\lambda\mathbf{p},0} \to \sqrt{n_0} e^{i\phi/2} \) and \( \hat{B}_{\lambda\mathbf{p},0}^\dagger \to \sqrt{n_0} e^{-i\phi/2} \). Next, we notice that at low temperatures, the momenta of uncondensed bosons are \( \mathbf{q} \ll mv \). Thus, we can expand the products of U-vectors in (13) in terms of the deviations
from the minima of the energy bands

\[ \tilde{U}_L^\dagger(q_1) \tilde{U}_L(q_2) = \tilde{U}_R^\dagger(q_1) \tilde{U}_R(q_2) \approx 1 - \frac{\Delta^2 (q_u - q_v)^2}{2 (mv)^2}, \]

\[ \tilde{U}_R^\dagger(q_1) \tilde{U}_R(q_2) = \tilde{U}_L^\dagger(q_1) \tilde{U}_L(q_2) \approx \frac{\Delta q_u + q_v}{mv}. \]

with \( \Delta = v'/v < 1 \) and corrections of order \( O(q_{1,2}^2) \) and \( O(q_{1,2}^3) \), respectively. Consequently, contributions to the mean-field Hamiltonian can be expanded in the small parameter \( x_q = \Delta^2 q_{1,2}^2/(mv)^2 \). In the zero-order approximation, i.e., neglecting contributions of order \( x_q \), the mean-field Hamiltonian for the \((n, N-n)\) sector is

\[ \hat{H}_n^{(0)} = \frac{N}{2V} \sum_{V_{\text{int}}(q)} \left[ \hat{B}_q (s(q) + 1 + \delta \sqrt{1 - \delta |e^{i\phi}|} - 1) \right] \hat{B}_q^\dagger + \hat{B}_q^\dagger T \left[ \frac{1}{\sqrt{1 - \delta^2}} \right] \hat{B}_q + \text{h.c.}, \]

where \( \delta = 2n/N - 1 \), \( \hat{B}_q \) \( (\hat{B}_L q, \hat{B}_R q) \) is the annihilation operator in a spinor notation, \( s(q) = 2 \delta E(q)/|\beta_0 V_{\text{int}}(q)| \), and \( \delta E(q) \) is the anisotropic spectrum near the minima. We now introduce new bosonic operators \( \hat{B}_{-q} = \sqrt{1 - n/N}\hat{B}_L q e^{-i\phi/2} - \sqrt{n/N}\hat{B}_R q e^{i\phi/2} \) and \( \hat{B}_{+q} = \sqrt{n/N}\hat{B}_L q e^{i\phi/2} + \sqrt{1 - n/N}\hat{B}_R q e^{-i\phi/2} \). The Hamiltonian becomes diagonal for the \( \hat{B}_{-q} \) particles, which have the “free” spectrum \( \delta E(q) \), and has the standard Bogoliubov form \( \delta E(q) \) for the \( \hat{B}_{+q} \) particles. Introducing the new operators \( \beta_{-q} = \hat{B}_{-q} \) and \( \beta_{+q} = (1 - A_{-q}^2)^{-1/2} (\hat{B}_{+q} + A_q \hat{B}_{+q}^\dagger) \), with

\[ A_q = -s(q) - 1 + \sqrt{s(q) + 1}^2 - 1, \]

we get

\[ \hat{H}_n^{(0)} = \xi_0(q) + \sum_q \left\{ \left[ \Omega_{-q} \beta_{-q}^\dagger \beta_{-q} + \Omega_+ (q) (\beta_{+q}^\dagger \beta_{+q}) \right] \right\}, \]

where \( \xi_0(q) \) is the condensate energy in the zero-order approximation, \( \Omega_{-q} = \{ q_x^2 + q_y^2 + q_z^2 [1 - (v'/v)^2] \}/(2m) \) is the anisotropic free particle quadratic spectrum and \( \Omega_+ (q) = \sqrt{\Omega_{-q} + n V_{\text{int}}(q)}^2 - n^2 V_{\text{int}}^2(q) \) is an anisotropic sound similar to the conventional Bogoliubov phonon mode in a BEC. At this level of approximation the condensate energy is \( n \)-independent (i.e., it is the same for any particular sector characterized by \( n \) left movers and \( (N-n) \) right movers) and, consequently, the degeneracy of the non-interacting ground state is preserved. In the first order approximation, the mean-field Hamiltonian \( \{11\} \) acquires sector-dependent corrections of order \( x_q \ll 1 \). Following the above recipe, we introduce a set of new operators \( \hat{B}_{\pm q} \) that diagonalize the \( \hat{B}_{-q}^\dagger \hat{B}_{-q} \) term in the Hamiltonian \( \{10\} \) but not the other terms. Next, we diagonalize the full Hamiltonian up to terms of order \( O(x_q^2) \) via a generalized Bogoliubov-type transformation

\[ \hat{\beta}_{-q} = \hat{B}_{-q} + x_{q} D_{q} \hat{B}_{-q}^\dagger + x_{q} F_{q} \hat{B}_{-q}^\dagger \]

\[ + x_{q} C_{q} \hat{B}_{-q} + x_{q} C_{q} \hat{B}_{-q}^\dagger \cdot \hat{B}_{+q}^\dagger \]

\[ \hat{\beta}_{+q} = \left( 1 - A_{+q}^2 \right)^{-1/2} \left( \hat{B}_{+q} + A_{q} \hat{B}_{+q}^\dagger \right) + x_{q} C_{q} \hat{B}_{-q} + x_{q} C_{q} \hat{B}_{-q}^\dagger . \]

In the equations \( \{18\} \) and \( \{19\} \) we already anticipated that some of the terms are corrections of order \( x_q \). The coefficients are determined by requiring that the \( \hat{\beta}_{-q} \) operators obey standard commutation relations \( \{ \text{to order } O(x_q^2) \} \) and that the off-diagonal contributions to the Hamiltonian vanish. Assuming for simplicity that we have a point-like interaction, i.e., \( V_{\text{int}}(q) = V_{\text{int}}(q) \) is momentum-independent for momenta in a range that is relevant for the problem, the groundstate energy in the \((n, N-n)\) sector is

\[ \mathcal{E}_0(n) = \frac{V_{\text{int}}N^2}{2V} + \frac{V_{\text{int}}N}{2V} \sum_{q \neq 0} \frac{1}{1 - A_q^2} \left\{ \left[ 2 + s(q) \right] A_q^2 + 2 A_q \right\} - \frac{x_q}{8} \left( A_q^2 (\cos(4\xi) + 3) - A_q^2 (\cos(4\xi) - 5) \right) + O(x_q^3), \]

where \( \cos^2(\xi) = n/N \). The relevant coefficient of the generalized Bogoliubov transformation \( \{18\}\{19\} \) has the form

\[ A_q = 1 - \frac{s}{2} + \frac{1}{2} \sqrt{4s(4+s) - \frac{x_q}{32}\sqrt{4s(4+s)}} \left( 2 + s \sqrt{4s(4+s)} \right) \times \left( -4 - 5s + (4+s) \cos(4\xi) \right) + O(x_q^3). \]

Explicitly evaluating \( \{20\} \) with \( A_q \) given by Eq. \( \{21\} \) shows that, at this level of approximation, the energy of the condensate becomes sector-dependent, \( \mathcal{E}_0(n) \approx \mathcal{E}_0^{(0)}(n) + \mathcal{E}_0^{(1)}(n) \), and is minimal for \( n = 0 \) and \( n = N \). Thus, the density-density interaction reduces the large \( (N+1) \)-fold degeneracy of the ground state to a two-fold degeneracy. Consequently, in the limit of vanishing interactions \( V_{\text{int}} \rightarrow +0 \), the most general expression for the many-body wave-function is

\[ |\Psi_N \rangle = \frac{1}{\sqrt{N!}} \left[ \sqrt{w_L e^{i\phi_L}} (\hat{B}_L^\dagger)^N + \sqrt{w_R e^{i\phi_R}} (\hat{B}_R^\dagger)^N \right] |\text{vac} \rangle, \]

where \( w_L/R \) represents the fraction of the left/right movers and \( \phi_L/R \) are arbitrary phases. Notice that Eq. \( \{22\} \) describes a fragmented or entangled BEC, unless \( w_L w_R = 0 \). I.e., the many-body state \( \{22\} \) does not correspond to the condensation into one single-particle state. We reiterate that the left- and right-movers in the condensate have non-zero momentum, but zero velocity and do not actually move while the laser fields responsible for the spin-orbit coupling are present. We also note that equation \( \{22\} \) describes a so-called NOON state \( \{23\} \) which is quantum correlated state with properties that can be exploited in applications such as quantum sensing
and quantum metrology. This suggests that the possibility of using spin-orbit coupled condensates as qubits deserves to be further investigated.

B. Gross-Pitaevskii equations

Let us consider the density-density interaction potential as a contact pseudo-potential, \( V_{\text{int}}(\mathbf{r}-\mathbf{r}') = V_{\text{int}} \delta(\mathbf{r}-\mathbf{r}') \), where \( V_{\text{int}} = \frac{4\pi \hbar^2 a}{m} \) and \( a \) is the inter-atomic scattering length. The full many body Hamiltonian can be written as

\[
\hat{H} = \sum_{\mu, \nu} \int d^3r \, \hat{\psi}_\mu^\dagger(\mathbf{r}) h_{\mu \nu} \hat{\psi}_\nu(\mathbf{r}) + \int d^3r \, \hat{\psi}_\mu^\dagger(\mathbf{r}) \hat{\psi}_\mu(\mathbf{r}),
\]

in terms of field operators \( \hat{\psi}_\mu(\mathbf{r}) \) for the original hyperfine states, \( \mu \in \{0, 1, 2, 3\} \). In Eq. \( \text{(23)} \) we used the notation \( h_{\mu \nu} = \left\{ \frac{\mathbf{p}^2}{2m} + V_{\text{trap}} + H_{a-1} \right\}_{\mu \nu} \) for the single particle Hamiltonian in the presence of a trap potential \( V_{\text{trap}} \), in addition to the spatially varying laser fields that interact with the atom, \( H_{a-1} \). In the adiabatic approximation, after projecting onto the dark state subspace, the first term in Eq. \( \text{(23)} \) becomes

\[
\sum_{\mathbf{p}, \alpha, \beta} \tilde{b}_{\mathbf{op}}^\dagger \left\{ \left[ \frac{\mathbf{p}^2}{2m} + V_{\text{trap}} \right] \mathbf{1} - v p_x \hat{\sigma}_z - v' p_y \hat{\sigma}_y \right\}_{\alpha \beta} \tilde{b}_{\mathbf{op}},
\]

where \( \tilde{b}_{\mathbf{op}}^\dagger \) and \( \tilde{b}_{\mathbf{op}} \) are the creation and annihilation operators for bosons with pseudo-spin \( \alpha = \uparrow, \downarrow \). The interaction term is given by equation \((22)\). Before writing down the Gross-Pitaevskii equations, let us summarize the three different representations used for describing the system of bosons interacting with the spatially modulated laser fields.

i) Hyperfine states representation: This is the most straightforward way to describe the motion of the bosons and their interaction with the trap potential (\( V_{\text{trap}} \)) and the laser fields (\( H_{a-1} \)), as well as the density-density interaction (second term in Eq. \( \text{(23)} \)). The field operator that creates a particle in the hyperfine state \( \mu \in \{0, 1, 2, 3\} \) at point \( \mathbf{r} \) is \( \hat{\psi}_\mu(\mathbf{r}) \), while the creation of a free-moving particle with momentum \( \mathbf{p} \) is described by \( \hat{c}_{\mathbf{p}}^\dagger = \int d^3r \, e^{i \mathbf{p} \cdot \mathbf{r}} \hat{\psi}_\mu^\dagger(\mathbf{r}) \). By performing the position-dependent rotation \( R_{\mu \alpha} \) which diagonalizes the atom-laser Hamiltonian and projecting onto the dark states subspace we switch to the pseudo-spin representation.

ii) Pseudo-spin representation (dark states representation): This is the natural framework for describing the low-energy physics of the atomic system interacting with the laser field. The creation operator for free-moving particles with spin \( \alpha \in \{\uparrow, \downarrow\} \) and momentum \( \mathbf{p} \) is \( \tilde{b}_{\mathbf{op}}^\dagger \). We can define the corresponding field operator as \( \hat{\psi}_\alpha(\mathbf{r}) = \sum_{\mu} e^{-i \mathbf{p} \cdot \mathbf{r}} \tilde{b}_{\mathbf{op}}^\dagger \). Note that the field operators in the hyperfine and pseudo-spin representations are related via the position-dependent rotation, \( \hat{\psi}_\mu^\dagger(\mathbf{r}) = \sum_{\alpha} R_{\mu \alpha}(\mathbf{r}) \hat{\psi}_\alpha(\mathbf{r}) \). Diagonalizing the single-particle spin-orbit coupled Hamiltonian, \( H = \left[ \frac{\mathbf{p}^2}{2m} + V_{\text{trap}} \right] \mathbf{1} - v p_x \hat{\sigma}_z - v' p_y \hat{\sigma}_y \), generates a set of eigenstates described by the spinor eigenfunctions \( \phi_{\sigma n}(\mathbf{r}) \). The quantum number \( \sigma = \pm \) can be viewed as labeling right (left) moving states.

iii) Right/left moving states representation: This is the representation corresponding to the eigenstates of the spin-orbit coupled single particle Hamiltonian. In Section \[ we have shown that in the absence of a trap potential the single particle spectrum for the generic case \( v \neq v' \) is characterized by two minima at non-zero momenta. Here we show explicitly that the double-degeneracy of the single-particle states is a general property of the spin-orbit interacting Hamiltonian, protected by a Kramers-like symmetry. Let us use the following parametrization for the eigenfunctions:

\[
\phi_{\sigma n}(\mathbf{r}) = e^{i \sigma n v x} \begin{pmatrix} u_{\sigma n}^\uparrow(\mathbf{r}) \\ i \sigma u_{\sigma n}^\downarrow(\mathbf{r}) \end{pmatrix},
\]

where \( \sigma = \pm \) and \( n \) is a set of quantum numbers. The components \( u_{\sigma n}^\uparrow(\mathbf{r}) \) are the solutions of the following eigenproblem

\[
\begin{pmatrix} h_0 - v' p_y & i p_x \\ -i p_x & h_0 + v' p_y \end{pmatrix} \begin{pmatrix} u_{\sigma n}^\uparrow(\mathbf{r}) \\ i \sigma u_{\sigma n}^\downarrow(\mathbf{r}) \end{pmatrix} e^{i \sigma n v x} = E_{\sigma n} \begin{pmatrix} u_{\sigma n}^\uparrow(\mathbf{r}) \\ i \sigma u_{\sigma n}^\downarrow(\mathbf{r}) \end{pmatrix} e^{i \sigma n v x},
\]

where \( h_0 = \frac{\mathbf{p}^2}{2m} + V_{\text{trap}} \) is the Hamiltonian in the absence of spin-orbit interaction. More explicitly, \( u_{\sigma n}^\uparrow(\mathbf{r}) \) satisfy the following system of coupled differential equations:

\[
\begin{align*}
\left[ -\frac{\nabla^2}{2m} + V_{\text{trap}}(\mathbf{r}) + iv' \frac{\partial}{\partial y} - E - \frac{m v^2}{2} \right] u_{\sigma}^\uparrow(\mathbf{r}) \\
- \left[ -i \sigma v \frac{\partial}{\partial x} + m v^2 \right] (u_{\sigma}^\uparrow(\mathbf{r}) - u_{\sigma}^\downarrow(\mathbf{r})) &= 0,
\end{align*}
\]

\[
\begin{align*}
\left[ -\frac{\nabla^2}{2m} + V_{\text{trap}}(\mathbf{r}) - iv' \frac{\partial}{\partial y} - E - \frac{m v^2}{2} \right] u_{\sigma}^\downarrow(\mathbf{r}) \\
- \left[ -i \sigma v \frac{\partial}{\partial x} + m v^2 \right] (u_{\sigma}^\uparrow(\mathbf{r}) - u_{\sigma}^\downarrow(\mathbf{r})) &= 0.
\end{align*}
\]

Taking the complex conjugate of \( \text{(26)} \) with \( \sigma \to -\sigma \) we obtain an identical set of equations. Consequently we have

\[
\begin{align*}
u_{\sigma}^\uparrow(\mathbf{r}) &= [u_{\sigma n}^\uparrow(\mathbf{r})]^*, \\
u_{\sigma}^\downarrow(\mathbf{r}) &= [u_{\sigma n}^\downarrow(\mathbf{r})]^*.
\end{align*}
\]

and the corresponding energies are degenerate, \( E_{-\sigma} = E_{\sigma n} = E_n \). Because \( \langle \phi_{-\sigma n} | \phi_{\sigma n} \rangle = 0 \), the two states are linearly independent. We conclude that the single-particle eigenstates of the spin-orbit coupled Hamiltonian are (at least) double degenerate independent of the
The non-interacting part of the Hamiltonian is diagonal in terms of left/right moving operators, with eigenvalues that depend on the momentum $q$ only. At low-energies, these eigenvalues are given by the anisotropic spectrum $\delta E(q) = (q_x^2 + q_y^2)/(2m) + q_y^2/(2m_y)$ with $m_y = m \left[1 - (v'/v)^2\right]^{-1}$. In general, the interacting Hamiltonian is given by equation (14), but in the low-energy limit we neglect all corrections of order $x_q = \Delta^2 q_y^2/(mv)^2$ and higher coming from the momentum-dependent matrices $U_{\alpha \sigma}(q)$. In this limit we obtain

$$i \frac{\partial}{\partial t} \tilde{\psi}_\sigma(r,t) = \left(\frac{-(i\partial_x - \sigma mv)^2}{2m} - \frac{\partial^2_y}{2m_y} - \frac{\partial^2_z}{2m_z}\right) \tilde{\psi}_\sigma(r,t) + V_{\text{int}} \left(\left|\tilde{\psi}_L\right|^2 + \left|\tilde{\psi}_R\right|^2\right) \tilde{\psi}_\sigma(r,t),$$

(31)

where $\partial_j = \partial/\partial x_j$, $j \in \{x, y, z\}$. The time-independent Gross-Pitaevskii equations can be obtained by looking for a stationary solution of the form $\tilde{\psi}_\sigma(r,t) = \tilde{\psi}_\sigma(r)e^{-i\mu t}$, where $\mu$ is the chemical potential which determined by the condition $N = \int d^3r \left(\left|\tilde{\psi}_L\right|^2 + \left|\tilde{\psi}_R\right|^2\right)$, with $N$ being the total number of bosons. We note that by linearizing $\tilde{\psi}_\sigma(r,t)$ with respect to the deviations from the stationary solution we obtain an excitation spectrum consisting in two modes, $\Omega_{\pm}(q)$, identical with those found using the generalized Bogoliubov treatment.

### IV. EXPERIMENTAL SIGNATURE OF SPIN-ORBIT COUPLED BEC: MEASURING A SOBEC QUBIT

A straightforward way to detect experimentally the new type of BEC would be to probe the momentum distribution of the density of the particles via time-of-flight expansion. After removing the trap and the laser fields, the boson gas represents a system of free particles, each characterized by a certain momentum and a hyperfine state index. In a TOF experiment one determines the momentum distribution by measuring the particle density at various times after the release of the boson cloud. The operator associated with a density measurement is $\hat{\rho}(r) = \sum_{\mu} \hat{\psi}_\mu^\dagger(r) \hat{\psi}_\mu(r)$, where $\hat{\psi}_\mu^\dagger(r)$ is the creation operator for a particle in the hyperfine state $\mu$ positioned at point $r$. Determining the density profile involves a simultaneous measurement of $\hat{\rho}(r)$ for all the values of $r \in \mathcal{V}$ corresponding to a certain region in space where the boson cloud is located. To insure formal simplicity, we consider a coarse-grained space, i.e., we treat $r$ as a discrete variable. This is simply a technical trick and does not influence the final result. Our goal is to find the most likely spatial distributions of the particles at a given moment $t$ after the release of the atoms. In the limit of large particle numbers, the actual measured density profiles will involve only small fluctuations away from these “most likely” distributions.
For a system of N bosons, the result of the measurement is a set of eigenvalues \( \{ \sum_{\mu} n_{\mu} \} \) that label an eigenvector of the density operator

\[
|\Phi_{\{n_{\mu}\}}\rangle = \prod_{\mu, r \in V} \frac{1}{\sqrt{n_{\mu}(r)}} \left[ |\psi_{\mu}(r)\rangle \right]^{n_{\mu}} |\text{vac}\rangle,
\]

where the occupation numbers satisfy the constraint \( \sum_{\mu} n_{\mu} N = N \), and the factors \( 1/\sqrt{n_{\mu}(r)} \) insure the normalization to unity. Note that \( n_{\mu}(r) \) is an integer representing the number of particles located in a certain “cell” \( r \) of the coarse-grained space. At time \( t \) after the release, the many-body state of N bosons that were initially in a BEC groundstate described by Eq. (22) is

\[
|\tilde{\Psi}(N)(t)\rangle = \sum_{\{n_{\mu}\}, V} N^{\frac{1}{2}} \sqrt{W_{\sigma}} e^{i\phi_{\sigma}} \prod_{\mu, r \in V} \frac{1}{\sqrt{n_{\mu}(r)}} \left[ Q_{\mu}^{\dagger}(r,t) |\psi_{\mu}(r)\rangle \right]^{n_{\mu}} |\text{vac}\rangle,
\]

where \( N \) is a normalization factor, \( \sigma \) labels the left (\( \sigma = L \equiv -1 \)) and right (\( \sigma = R \equiv +1 \)) modes and \( |\tilde{\Psi}(N)(0)\rangle = |\Psi(N)\rangle \). The coefficients \( Q_{\mu}^{\dagger} \) are normalized so that \( \sum_{\mu, r} \left| Q_{\mu}^{\dagger}(r,t) \right|^2 = 1 \). The second summation in Eq. (33) is over all possible spatial distributions of \( N \) particles and, in the continuous limit, it becomes a path integral. Equation (33) represent the expansion of the many-body wave-function in terms eigenstates (32) of the density operator. The probability \( \mathcal{P}\{\{n_{\mu}\}\} \) of measuring a certain density profile \( n_{\mu} \) is determined by the coefficient of the corresponding term. If we focus, for simplicity, on the case when there are only left (right) movers in (22), this probability is proportional to \( \prod_{\mu, r} \left| Q_{\mu}^{\dagger}(r,t) \right|^{2n_{\mu}} \), with \( \sigma = L(R) \). The probability \( \mathcal{P}\{\{n_{\mu}\}\} \) has a maximum for \( n_{\mu}^0 = N Q_{\mu}^{\dagger}(r,t) \) corresponding, in the continuous limit, to a stationary point of the path integral in equation (33). For large particle number, \( \mathcal{P}\{\{n_{\mu}\}\} \) becomes sharply peaked at \( n_{\mu}^0 \) and the actually measured density profiles will exhibit only relatively small deviations from the stationary profile. Therefore, at time \( t \) after release, the density of the boson cloud is

\[
\rho(r,t) = N \sum_{\mu} \left| Q_{\mu}^{\dagger}(r,t) \right|^2.
\]

If both \( w_R \) and \( w_L \) are non-zero, the result of a measurement will be either a “right moving” density profile \( \sigma = R \) in (33) with a probability \( w_R \), or a “left moving” profile \( \sigma = L \) in (33) with a probability \( w_L \), assuming that the two profiles are spatially well separated. We are not addressing here the interesting effects of the interference between left and right moving condensates. These effects are negligible if the left and right moving density profiles are spatially separated, but become important otherwise, e.g. at small times after the release.

Next we determine explicitly the coefficients \( Q_{\mu}^{\dagger}(r,t) \) for the exactly solvable model of bosons with “Ising-type” spin-orbit coupling, \( v \neq v' = 0 \), placed in a harmonic trap, \( V_{\text{trap}}(r) = mw^2r^2/2 \). In this case, the operators \( B_{\sigma}^{\dagger} \) from Eq. (22) are creation operators for the single particle ground states

\[
\varphi_0(r)e^{i\sigma \text{mvz}} \frac{1}{\sqrt{2}} \left( \begin{array}{c} 1 \\ i\sigma \end{array} \right),
\]

where \( \varphi_0(r) \) represents the ground state wavefunction of the harmonic oscillator. The spinor \( \Psi_0(0) \) is written in the dark state basis. Performing the position-dependent rotation \( R_{\mu \alpha} \) [see Eq. (33)], we can express the operators \( B_{\sigma}^{\dagger} \) in terms of creation operators for particles in a certain hyperfine state located at point \( r \), \( \tilde{\psi}_{\mu}(r) \), or their Fourier components corresponding to free moving particles, \( \tilde{c}_{\mu k}^{\dagger} \). The time evolution after the release can be easily described in terms of time evolution for the \( \tilde{c}_{\mu k}^{\dagger} \) operators, \( \tilde{c}_{\mu k}^{\dagger}(t) = \exp(-i\epsilon_k t) \tilde{c}_{\mu k}^{\dagger} \), where \( \epsilon_k = k^2/(2m) \) is the free particle spectrum. Consequently, the many-body state \( |\tilde{\Psi}(N)(t)\rangle \) can be obtained by making in Eq. (22) the substitution \( B_{\sigma}^{\dagger} \rightarrow \sum_{\mu, r} Q_{\mu}^{\dagger}(r,t) \tilde{\psi}_{\mu}(r) \) with

\[
Q_{\mu}^{\dagger}(r,t) = \sum_{\alpha, k, r'} \left[ \varphi_\alpha^\dagger \right] \left( r' \right) R_{\mu \alpha}^{\dagger}(r') e^{i(k \cdot r') - i\epsilon_k t}.
\]

Finally, introducing this expression of \( Q_{\mu}^{\dagger} \) in equation (33) we obtain for the measured density profile the expression

\[
\rho(r,t) = N \sum_{\mu} \frac{\Gamma^3}{2\pi (1 + \tau^2)^{\frac{3}{2}}} e^{-r^2/2 \tau^2 (1 + \tau^2)} \left[ \sin^2 \theta e^{-\lambda^2 / 2 \tau^2 (1 + \lambda^2)} \right]^2 + (1 - \lambda \cos \theta)^2 e^{-r^2/2 \tau^2 (1 + \lambda^2)} \left[ \sin^2 \theta e^{-\lambda^2 / 2 \tau^2 (1 + \lambda^2)} \right]^2 + (1 + \lambda \cos \theta)^2 e^{-r^2/2 \tau^2 (1 + \lambda^2)} \left[ \sin^2 \theta e^{-\lambda^2 / 2 \tau^2 (1 + \lambda^2)} \right]^2,
\]

where \( \lambda = \sqrt{m} \) is the inverse characteristic length of the trap potential, \( \tau = \omega t \) is time in units of \( \omega^{-1} \), \( \theta \in [0\pi/2] \) and \( \lambda \) are tunable parameters characterizing the laser field, and \( v = v_a \cos \theta \) [see the paragraph containing Eq. (33)]. In equation (37) the density was normalized so that \( \int d^3r \rho(r,t) = N \). The density profile for a “left moving” density distribution (\( \sigma = -1 \)) is shown in Fig. 4 for three different times after the release of the boson cloud. The parameters of the calculation are \( \theta = \pi/3 \) and \( v_a = 6\sqrt{\omega}/m \). Notice the three-peak structure of the density, corresponding to the three exponential terms in equation (37). The relative weights of the peaks are \( \cos^2(\theta/2) \) (large peak), \( 1/2 \sin^2 \theta = 2 \cos^2(\theta/2) \cos^2(\theta/2) \) (middle peak) and \( \sin^4(\theta/2) \) (small peak) and their characteristic velocities are \( -\sigma v_a (1 - \cos \theta) \), \( \sigma v_a \cos \theta \) and \( \sigma v_a (1 + \cos \theta) \), respectively. The “left” and “right moving” distributions are symmetric with respect to a \( x \rightarrow -x \) reflection (see also Fig. 4). Notice that the total momentum corresponding to a distribution described by equation (37) vanishes. By analyzing the transformation (3) to the
dark state basis, we observe that $\sin \theta$ is the coefficient of the hyperfine state $|3\rangle$. Consequently, the middle peak in the density distribution represents S. T. light consists of particles in this particular hyperfine state. The other two peaks contain mixtures of states $|1\rangle$ and $|2\rangle$. A state-selective measurement of particles in the hyperfine state $|3\rangle$ would reveal a single peak structure moving to the left or to the right with a velocity $v = v_a \cos \theta$. The dependence of the density profile $\rho(r, t)/N$ on $\theta$ and on the ratio $\gamma = v_a/\sqrt{\omega/m}$ for $r = (x, 0, 0)$ and $t = \omega^{-1}$ is shown in Fig. 4.

**V. SUMMARY AND CONCLUSIONS**

To summarize, in this article we have introduced and discussed in detail a new type of many-body system consisting of pseudo-spin-$1/2$ bosons with spin-orbit interactions. We have shown that at low temperatures the system condenses into a new type of entangled BEC, the spin-orbit coupled Bose-Einstein condensate (SOBEC). The novelty of this state stems from the coupling of an internal degree of freedom, the pseudo-spin created as a result of an atom interacting with a spatially modulated laser field, to the real space motion of the particles. As a result, the single-particle spectrum is characterized by degenerate minima at finite momenta and, consequently, the bosons condense at low temperatures into an entangled quantum state with non-zero momentum. For an arbitrary spin-orbit coupling, the single particle spectrum has a double-well structure in momentum space (see Fig. 1) with minima at non-zero momenta. In this case, a system of $N$ non-interacting bosons is characterized by a large $(N + 1)$-fold degeneracy of the many-body ground state. Weak density-density interactions reduce this large degeneracy to a two-fold degeneracy. The corresponding ground state wave-function describes a superposition of left-moving and right-moving condensates with weights $w_L$ and $w_R = 1 - w_L$, respectively. Performing a time-of-flight expansion of the condensed bosons results in a characteristic three-peak structure (see Fig. 2). The total momentum of the density profile is identically zero, but the peaks are moving along the x-direction with velocities proportional to the k-vector of the laser field modulation in that direction. The probability of measuring a left- (right-) moving condensate is $w_L$ ($w_R$) and the signature of a left- (right-) moving state consists in the middle and small peaks moving left (right), while the large peak moves in the opposite direction.

In conclusion, the spin-orbit coupled BEC can be viewed as a state occurring at the interface between spintronics and cold atom physics, with nontrivial properties that have a significant potential for applications. We note here that the ground-state of the double-well SOBEC [see Eq. (22)] represents a NOON state $|\lambda=0\rangle$, similar to those recently proposed for the construction of a graviometer based on atom interferometry. Therefore, the study of a SOBEC state in the context of quantum entanglement...
and quantum interference is highly relevant. In addition, the double degeneracy associated with the pseudo-spin degree of freedom makes this state a natural candidate for a qubit. A possible way to measure such a qubit was described in the last section. Time-dependent laser fields [similar to those, which lead to the spin-orbit-coupled Hamiltonian (1)] could be used as “gates” to perform unitary rotations in the space of degenerate ground states. Note that the coupling of the spin to the orbital motion yields a protecting mechanism against decoherence, due to momentum conservation, and suggest that the spin-orbit coupled condensates are interesting candidates for fault tolerant quantum computation. Finally, we note that for a symmetric Rashba-type spin-orbit coupling the system is characterized by a single-particle spectrum that has a continuous set of minima along a circle in momentum space. This results in a huge degeneracy that may lead to possible phases with non-trivial topological properties, making the study of the symmetric SOBEC a potentially very interesting problem.
