INTRODUCTION

Kawasaki disease (KD) is an acute febrile multisystem vasculitis and has been recognized to be one of the most common causes of acquired heart disease in children. KD with gastrointestinal bleeding is quite rare. We report a 12-month-old boy with KD complicated by gastrointestinal hemorrhage after using of high-dose of aspirin. Physicians caring for patients with KD should mind on the signs and symptoms of aspirin toxicity including gastrointestinal hemorrhage. Starting or early switching to a low-dose aspirin treatment on KD should be considered.

Keywords: Kawasaki disease; Gastrointestinal hemorrhage; Aspirin; Ulcer

CASE REPORT

A previously healthy, 12-month-old boy was hospitalized with 3 days of typical signs of KD: fever, bilateral non-exudative conjunctivitis, erythema of the lips and oral mucosa, body rash and neck swelling. Initial laboratory tests showed a hemoglobin concentration of 10.1 g/dL, white blood cell count of 21,200 /mm³, platelet count of 423,000 cells/µL, Erythrocyte sedimentation rate of 72 mm/hr, and C-reactive protein level of 9.1 mg/dL.

On the second day of admission, high-dose aspirin therapy (100 mg/kg/day) was started. however, KD symptoms persisted. On day 3, IVIG administration (2 g/kg/day) was started. After IVIG administration, fever persisted for more
than 36 hours, and a second regimen of IVIG was administered on day 5. On the same day, the patient looked pale and showed decreased consciousness. Vital signs were as follows: blood pressure was 70/40 mmHg; heart rate was 170 beats per minute; respiratory rate was 60 breaths per minute, and saturation on room air was 90%. Laboratory tests showed a hemoglobin concentration of 2.5 mg/dL, platelet count of 257,000 cells/µL, alanine aminotransferase of 27 u/L, aspartate aminotransferase of 21 u/L, prothrombin time of 22.2 seconds (INR 2.04), and partial thromboplastin time of 58.8 seconds, antithrombin III 57%, D-dimer 20.9 µg/mL. We diagnosed hypovolemic shock with disseminated intravascular coagulation. He received massive blood transfusion and was transferred to the pediatric intensive care unit. We performed computed tomography (CT) scans of the brain and gastrointestinal tract to find the bleeding site. A hematoma in the stomach was observed on abdominal CT (Fig. 1). A large amount of blood clot was observed through the nasogastric tube, and melena was observed on the next day. A diagnosis of upper gastrointestinal bleeding was made. Esophagogastroduodenoscopy (EGD) could not be performed immediately because of the patient’s unstable vital signs. We stopped high-dose aspirin therapy and administered high-dose proton pump inhibitor and octreotide. On day 9, his hemoglobin level (11.2 g/L) and blood pressure (90/60 mmHg) normalized. Echocardiography performed on days 3, 7, 11 and 21 showed no abnormalities. EGD performed on day 22 showed a healing ulcer on the bulb of the duodenum (Fig. 2A). After maintaining proton pump inhibitor therapy for six weeks, the disappearance of the ulcer was confirmed by follow-up EGD (Fig. 2B). The patient was followed up with an echocardiography in the outpatient clinic without aspirin treatment, and there was no coronary artery (CA) complication.

Fig. 1. Abdominal CT presents a hematoma (arrow) in the stomach.

Fig. 2. EGD findings: (A) on day 22, showing a healing ulcer (arrow) on the bulb of duodenum. (B) Follow-up EGD (two months later) findings show the healing ulcer has disappeared.
DISCUSSION

KD is a systemic, idiopathic vasculitis that occurs predominantly in infants and children younger than 5 years. [1,2,7] The most significant complication is coronary artery abnormalities (CAA) including aneurysms which occurs in 20-25% of untreated children [2,7].

Over decades, IVIG and aspirin have been considered the standard initial treatment of KD. The incidence of CAA on morbidity and mortality have dramatically decreased as a result of IVIG treatment. Aspirin was one of the first treatments used for KD because of its anti-inflammatory and antiplatelet effects [7]. But the role and appropriate dose of aspirin is still unclear during the acute phase of illness [8]. Moreover, it is not certain that the IVIG combined with aspirin provides greater anti-inflammatory effects than IVIG alone. Several meta-analyses have shown that aspirin does not affect aneurysm formation [9,10]. The dose of aspirin needed to achieve anti-inflammatory effects during the acute phase of illness is relatively high, with a recommended range of 30-100 mg/kg per day in four divided doses. In North America, high-dose (80-100 mg/kg per day) aspirin is most widely used during the acute phase. In Japan, concern about hepatic toxicity have led to the use of moderate dose (30-50 mg/kg per day) aspirin as a recommended standard therapy in the acute phase [1,11,12].

The risks of aspirin therapy are low and appear to be similar to those reported in other settings, including chemical hepatitis with elevated transaminases, transient hearing loss, dose-related hemolytic anemia [13], and rarely, Reye syndrome. Gastrointestinal hemorrhage is reported in patients administered high-dose aspirin after being diagnosed with KD [3,5]. We describe each cases: a 2-year-old boy diagnosed with KD took aspirin (71 mg/kg/day) during the acute phase and experienced acute gastrointestinal bleeding after 13 days of aspirin treatment. EGD revealed an ulcer (2 cm in size) in the duodenum [3]. A 4-year-old girl who took aspirin (100 mg/kg/day) experienced melena followed by emesis of blood on day 26 of aspirin treatment. She did not have an endoscope [3]. A 5-year-old boy had tarry stool on day 6 of fever without taking aspirin. But three days later, he was treated with aspirin (80 mg/kg/day) and massive GI bleeding occurred on day 5 of aspirin treatment [4]. A 3-year-old boy who took aspirin (50 mg/kg/day) experienced hematochezia on the third day after taking aspirin. Multiple rectal superficial ulcers were observed in colonoscopy [5]. The cases are summarized in Table 1. All cases were patients who took doses of aspirin higher than 50 mg/kg/day. Our case took aspirin at a dose of 100 mg/kg/day.

Aspirin can cause GI mucosal damage from prostaglandin depletion via inhibition of cyclooxygenase-1. Prostaglandins play a pivotal role in protecting gastric mucosal integrity via increasing local blood flow and promoting the synthesis and secretion of mucus and bicarbonate. In the absence of

| Case | Age | Sex | Details of gastrointestinal bleeding | Transfusion | Endoscopy | Aspirin dose |
|------|-----|-----|------------------------------------|-------------|-----------|-------------|
| Matsubara et al. | 1 | 2 y | M | Hematemesis on day 19 (day 13 of aspirin) | Yes | 2 cm sized duodenal ulcer (+) | 71 mg/kg/d |
| | 2 | 4 y | F | Melena followed by emesis of blood on day 31 (day 26 of aspirin) | Yes | None (+) | 100 mg/kg/d |
| Chang et al. | 3 | 5 y | M | Tarry stool on day 6 (without aspirin) Massive GI bleeding on day 14 (day 5 of aspirin) | Yes | Not available (+) | 80 mg/kg/d |
| Han et al. | 4 | 3 y | M | Hematochezia (day 3 of aspirin) | No | Multiple superficial ulcers in rectum (+) | 50 mg/kg/d |

normal prostaglandin synthesis, the gastric environment becomes more vulnerable to exogenous (i.e. smoking) or endogenous factors (i.e. H. pylori, acid, pepsin, and bile salts) and consequently, more prone to developing peptic ulcers and bleeding complications [14].

Gastrointestinal bleeding has been reported in patients with KD who did not use aspirin [6]. Without aspirin use, gastrointestinal bleeding may occur as a complication of KD. The exact mechanism is not known, but it is speculated that vasculitis in the gastrointestinal tract or KD-related stress may be the cause of bleeding in the gastrointestinal tract.

Gastrointestinal bleeding is rare in patients with KD [3, 5, 15]. However, attention should be paid to the occurrence of gastrointestinal bleeding. Many studies have reported that aspirin treatment does not reduce the incidence of coronary artery complications [16, 17]. Several studies showed no significant difference between aspirin doses and IVIG resistance rates, CA lesion formation, duration of hospitalization [16-18].

In order to prevent gastrointestinal bleeding, we should consider that administer a dose of less than 50 mg/kg/day and switch to a low-dose of aspirin as soon as symptoms are improved. We can also consider starting with a low-dose aspirin from the beginning or PPI treatment for prophylaxis on KD during the acute phase.

Physicians caring for patients with KD should instruct parents on the signs and symptoms of aspirin toxicity including gastrointestinal hemorrhage and should always be mindful of the possibility of gastrointestinal bleeding that can occur when taking aspirin.
