Abstract. We have tried to give an overview of model-independent semi-analytical approach to study the observational constraints on reionization. We have implemented and investigated a method to do a detailed statistical analysis using principal component analysis (PCA) technique. We have also discussed different observations related to reionization and shown how to use PCA for constraining the reionization history. Using Markov Chain Monte Carlo methods, we have found that all the quantities related to reionization can be severely constrained at $z < 6$, whereas a broad range of reionization histories at $z > 6$ are still permitted by the current data sets. We have shown that with the forthcoming PLANCK data on large-scale polarization, the $z > 6$ constraints will be improved considerably.

1. Introduction
In the past few years, the understanding of reionization process has become increasingly sophisticated in both the observational and theoretical communities, thanks to the availability of good quality data related to reionization. Mainly, the observations by the Wilkinson Microwave Anisotropy Probe (WMAP) satellite of cosmic microwave background (CMB) and highest redshift quasars put very tight constraints on the reionization history of the universe. The physical processes relevant to reionization are so complex that neither the analytical nor the numerical simulations alone can capture the overall picture. That is why, it is often studied using semi-analytical models of reionization, with limited computational resources. The semi-analytical model used in this work is based on Choudhury and Ferrara [1, 2]. This model treats the inter-galactic medium (IGM) as multi-phase medium, and takes into account the inhomogeneities in the IGM. The sources of ionizing radiation taken, here, are stars and quasars. The model computes radiative feedback (suppressing star formation in low-mass haloes using a Jeans mass prescription) self-consistently from the evolution of the thermal properties of the IGM. The major uncertainty in modelling any semi-analytical reionization scenario is to model the parameter $N_{\text{ion}}$, the number of photons entering the IGM per baryon in collapsed objects.

2. Principal component analysis
Most likely, $N_{\text{ion}}$ is a function of halo mass and the redshift, but the dependences are not well understood, and that is why it is usually taken to be a constant. A method which is ideally suited to tackle this problem is to use the principal component analysis (PCA); this is a technique to compute the most meaningful basis to re-express the unknown parameter set, and the hope is that this new basis will reveal hidden detailed statistical structure [3, 4].

In this paper, we have assumed $N_{\text{ion}}(z)$ to be an unknown function of $z$ and decompose it into principal components. We have included only one stellar population and hence, there...
should not be any explicit chemical feedback in our model. A detailed likelihood analysis is
done using three different data sets: The photoionization rates \( \Gamma_{\text{PI}} \), obtained using Ly-\( \alpha \) forest
Gunn-Peterson optical depth observations and a large set of hydrodynamical simulations, the
redshift distribution of LLS d\( N_{\text{LL}}/dz \) at \( 0.36 < z < 6 \), and the angular power spectra \( C_l \) for
TT, TE and EE modes using WMAP-7 and forecasted PLANCK data. The moment we have
included the \( C_l \)'s (TT+TE+EE) in our analysis, we have realized that parameters related to
reionization may have strong degeneracies with (some of) the cosmological parameters, mainly
with the normalization of the matter power spectrum \( \sigma_8 \) and the slope \( n_s \), so we have carried
out our analysis by varying only these two parameters (in addition to the parameters related
to reionization model) and keeping all the other cosmological parameters fixed to their best-fit
WMAP-7 value.

2.1. Formalism

We have represented the unknown function \( N_{\text{ion}}(z) \) by a set of \( n_{\text{bin}} \) discrete free parameters with
redshift bins. Then we have constructed the Fisher matrix:

\[
F_{ij} = \sum_{\alpha=1}^{n_{\text{obs}}} \frac{1}{\sigma_\alpha^2} \frac{\partial G^\text{th\_fid}_\alpha}{\partial N_{\text{ion}}(z_i)} \frac{\partial G^\text{th\_fid}_\alpha}{\partial N_{\text{ion}}(z_j)},
\]

where \( G_\alpha, \alpha = 1, 2, \ldots, n_{\text{obs}} \) represent the observational data points, \( \sigma_\alpha \) are their corresponding
error, \( G^\text{th\_fid}_\alpha \) is theoretical value of \( G_\alpha \) and \( N_{\text{ion}}^\text{fid} \) is the fiducial model, which is, in principle,
close to the underlying “true” model. Here, we have taken the fiducial model \( N_{\text{ion}}^\text{fid} \) to be the
one, which matches the current data points up to an acceptable accuracy, and also which is
characterized by a higher \( N_{\text{ion}} \) at higher redshifts. Once the Fisher matrix is constructed, we
can determine its eigenvalues and corresponding eigenvectors. Because of the ortho-normality and
completeness of the eigenfunctions, we can expand the deviation of \( N_{\text{ion}} \) from its fiducial
model as \( \delta N_i = N_{\text{ion}}(z_i) - N_{\text{ion}}^\text{fid}(z_i) = \delta N_i = \sum_{k=1}^{n_{\text{bin}}} m_k S_k(z_i) \), where \( S_k(z_i) \) are the principal
components of \( N_{\text{ion}}(z_i) \), and \( m_k \) are the expansion coefficients. The advantage is that, unlike
\( N_{\text{ion}}(z_i) \), the coefficients \( m_k \) are uncorrelated with variances. It can be shown that the largest
eigenvalues correspond to minimum variance and vice versa. Hence, most of the information
relevant for the observed data points is contained in the first few modes with larger eigenvalues.
We can then reconstruct the function \( \delta N_i \) using only the first \( M \leq n_{\text{bin}} \) modes. So, the important
step in this analysis is to decide on how many modes \( M \) to be used.

3. Results: WMAP-7 vs PLANCK

3.1. The principal components of \( N_{\text{ion}}(z) \)

We have found that the components of the Fisher matrix vanish for \( z < 2 \), because there are
no data points considered at these redshifts. For \( 2 < z < 6 \), the values of \( F_{ij} \) are considerably
higher, because it is determined by the sensitivity of \( \Gamma_{\text{PI}} \) and d\( N_{\text{LL}}/dz \) on \( N_{\text{ion}}(z) \). On the
other hand, the information at \( z > 6 \) is determined by the sensitivity of \( C_l^{EE} \) on \( N_{\text{ion}} \), which is
relatively weak. We have found that \( F_{ij} \) is negligible for \( z > 14 \), and this is expected because the
collapsed fraction of haloes is negligible at those redshifts, and hence, there exist no free
electrons to contribute to electron scattering optical depth \( \tau_{el} \) or \( C_l^{EE} [5, 6] \). In Figure 1, we have
shown the inverse of the first few eigenvalues \( \lambda_i \), i.e., the variances of the corresponding modes.
For modes \( i > 8 \), the eigenvalues are almost zero, and the variances are extremely large. This
implies that the errors on \( N_{\text{ion}} \) would increase dramatically if we include modes \( i > 8 \). The first 8
eigenmodes (i.e., those which have the lowest variances) are plotted in Figure 2. We have found
that all the eigenmodes tend to vanish at \( z < 2 \) and \( z > 15 \), which is obvious because of \( F_{ij} \) being
negligible at these redshifts. We can see a number of spikes and troughs in the first four modes,
whose positions correspond to the presence of data points for \( \Gamma_{\text{PI}} \) and d\( N_{\text{LL}}/dz \) at \( 2 < z < 6 \).
The last four modes contain the information about the sensitivity of \(C_{EE}^l\). The modes (> 8) with smaller eigenvalues, i.e., large variances introduce huge uncertainties in the determination of \(N_{\text{ion}}\), and hence, do not contain any meaningful information about the reionization history.

3.2. Choice of the number of modes

The next step in our analysis is to decide on how many modes \(M\) to use. A sophisticated and model-independent prescription is to use Akaike information criterion (AIC = \(\chi^2_{\text{min}} + 2M\)), where smaller values of AIC are assumed to imply a more favoured model. Note that there is no reason to select one particular reconstruction, the minimum of AIC can be accompanied by an increased chance of getting the reconstructed parameters wrong. One successful strategy for this purpose is to select different \(M\), which are near the minimum value of AIC and amalgamate them equally at the Monte Carlo stage when we compute the errors [7]. In this way, we can reduce the inherent bias, which exists in any particular choice of \(M\). We have examined that, in our case, the family of different \(M\) reconstructions, starting from \(M = 2\), which satisfy AIC < AIC_{\text{min}} + \kappa, where \(\kappa = 10\) (which corresponds to \(M = 8\)) produces very solid results. For alternative data sets, the value of \(\kappa\) can be adjusted.

3.3. Markov Chain Monte Carlo constraints

The constraints on reionization are obtained by performing a Monte Carlo Markov Chain (MCMC) analysis over the parameter space of the optimum number of PCA amplitudes and other free parameters of the model. To avoid the confusion about the correct choice of number of modes, we have performed the MCMC analysis for PCA amplitudes taking from \(M = 2\) to \(M = 8\), all of which obey the AIC criterion.

It can be seen from the plot of \(N_{\text{ion}}(z)\) (top-left panel of Figure 3) that such quantity must necessarily increase from its constant value at \(z < 6\). This rules out the possibility of reionization with a single stellar population having non-evolving IMF and/or star-forming efficiency. From the plot of \(\Gamma_{\text{Pl}}(z)\) (top-middle panel) and \(dN_{\text{LL}}/dz\) (top-right panel), we have found that the mean model is consistent with the observational data at \(z < 6\), as expected. The errors corresponding to 95% confidence limits are also smaller at this epoch. However, the model described by the mean values of the parameters shows a sharper and prominent peak around \(z \sim 6.5\) for both cases. From the plot of the volume filling factor of ionized region \(Q_{\text{HII}}(z)\) (bottom-left panel), we have seen that the growth of this quantity for the mean model is much faster than that of fiducial model at initial stages, though the completion of reionization takes
Figure 3. The marginalized posteriori distribution of various quantities related to reionization history obtained from the PCA using the AIC criterion with first 8 eigenmodes for WMAP-7 data.

place only at $z \approx 6$. Similarly, the neutral hydrogen fraction $x_{\text{HI}}(z)$ (bottom-middle panel) decreases much faster than the fiducial one at $6 < z < 12$ and then smoothly matches the Ly-$\alpha$ forest data. Finally, we have shown the values of (a) $C^\text{TT}_l$, (b) $C^\text{TE}_l$ and (c) $C^\text{EE}_l$ for the mean model in the bottom-right panel of this figure, which is almost the same as the fiducial model. Also, here, we have got the value of $\tau_{\text{el}}$ higher than the current WMAP value. So, a wide range of reionization histories is still allowed by the data we have used.

To check how better the PLANCK data can constrain the reionization scenario, we have first generated the simulated PLANCK data of CMB power spectra for our fiducial model up to $l \leq 2000$ using the exact full-sky likelihood function at PLANCK-like sensitivity, and then repeat the same MCMC analysis as we have done for WMAP-7 data. In Figure 4, we have illustrated the recovery of the same quantities as mentioned in the earlier case. We have found that our main results are in quite reasonable agreement with those obtained from the WMAP data, except that all the $2\sigma$ ($95\%$) limits are reduced remarkably for all redshift range, especially the $2\sigma$ limits for $Q_{\text{HII}}$ reduces significantly for this case. Thus, with the forthcoming PLANCK data on large scale polarization (ignoring the effect of foregrounds), the $z > 6$ constraints will be improved considerably. In particular, we have found that using the PLANCK data, the $2\sigma$ error on $\tau_{\text{el}}$ will be reduced to 0.009 and the uncertainties on the redshift at which reionization is 50% completed, i.e., $z(Q_{\text{HII}} = 0.5)$ and almost or 99% completed, $z(Q_{\text{HII}} = 0.99)$, would be $\sim 1$ and 3 ($95\%$ CL) respectively, which are much smaller than the case for current WMAP data. However, for more stringent constraints on reionization at $z > 6$, one has to rely on the data sets other than CMB.
