Origin of the $Q^2$-Dependence of the DIS Structure Functions

B. I. Ermolaev, M. Greco, and S. I. Troyan

Abstract—We consider in detail $Q^2$-dependence of the DIS structure functions. Very often this dependence is claimed to be originated by the $Q^2$-dependence of the QCD coupling. This leads to the small-$x$ asymptotics of the structure functions with $Q^2$-dependent intercepts. We demonstrate that the DGLAP parametrization $\alpha_s = \alpha_s(Q^2)$ is an approximation valid in the region of large $x$ (where $2pq$ can be approximated by $Q^2$) only, providing the factorization scale is also large. Outside this region, the DGLAP parametrization fails, so $\alpha_s$ should be replaced by an effective coupling which is independent of $Q^2$ at small $x$. As a consequence, intercepts of the structure functions are independent of $Q^2$. Nevertheless, the small-$x$ asymptotics of the structure functions explicitly depend on $Q^2$, even when the coupling does not depend on it. We also consider the structure functions at small $Q^2$ and give a comment on power-$Q^2$ corrections to the structure functions at large and small $Q^2$.

1. INTRODUCTION

Each of the DIS structure functions has two independent arguments: the invariant energy $w = 2pq$ (with $p$ and $q$ being the hadron target and virtual photon momenta respectively) and virtuality of the incoming photon $Q^2 = -q^2 > 0$. Early experiments of 60s at SLAC proved that the structure functions depended on only one argument $x = Q^2/w$. This phenomenon was called scaling. Later, new experiments proved that the scaling was violated i.e. in addition to $x$-dependence the DIS structure functions also depended on $Q^2$ straightforwardly. Since that it become conventional to regard variables $x$ and $Q^2$ as independent arguments of the structure functions. However, one has to realize that those arguments (in contrast to the set of really independent arguments $w$, $Q^2$) cannot be regarded as independent variables at all times. Indeed, they are independent when $Q^2$ is fixed while $w$ is scanned but they are not independent at fixed $w$ and scanned $Q^2$. The $Q^2$-dependence of the structure functions is the objective of the DGLAP evolution equations [1] implementing the total resummation of $\ln Q^2$. In DGLAP and beyond this approach, the $Q^2$-dependence of the structure functions is often thought to be induced by the $Q^2$-dependence of $\alpha_s$: 

$$\alpha_s = \alpha_s(Q^2).$$  \hspace{1cm} (1)

As this parametrization takes place in the DGLAP equations [1], throughout the present paper we will address it as the DGLAP-parametrization. Parametrization (1), originally deduced for large $x$, where $2pq$ can be approximated by $Q^2$, is often exploited to describe DIS in the small-$x$ region and even in the small-$x$ asymptotic of the structure functions, i.e. at $x \rightarrow 0$ (see e.g. [2–6]). As a result, the small-$x$ asymptotics look like

$$f \sim x^{-\Delta(Q^2)},$$  \hspace{1cm} (2)

with the $Q^2$-dependence of the asymptotics originated by the “intercept” $\Delta(Q^2)$.

In the present paper we argue against both validity of Eq. (2) and treating Eq. (1) as an exact formula which could be used at any $x$ and $Q^2$. In what follows we will show that the parametrization (1) should be used with a certain care: it can be used within the proper DGLAP kinematic region, i.e. at large $x$ and $Q^2$, however it is not enough: the factorization scale should also be large. We show that if any of these requirements is violated, $\alpha_s(Q^2)$ should be replaced by the effective coupling which does not depend on $Q^2$ at small $x$ as well as at small $Q^2$. The effective coupling, being independent of $Q^2$ at small $x$, cannot bring any $Q^2$-dependence to the structure functions. In this case the $Q^2$-dependence of the structure functions is originated by alternative sources. We also argue against regarding the approximative parametrization (1) as the basis for the shift $\alpha_s(Q^2) \rightarrow \alpha_s(Q^2 + \mu^2)$ as a continuation into the small-$Q^2$ region when the shift is used in order to keep $\alpha_s$ in the perturbative domain. Instead we suggest an alternative approach to describe the structure functions in the small-$Q^2$ region.

Our paper is organized as follows: In Section 2 we consider the DIS structure functions in general, focus-
ing on their conventional dependence on $Q^2$. In Section 3 we consider the structure functions in the framework of DGLAP and discuss parameterizations of the QCD coupling in different kinematic regions. In Section 4 we derive a general expressions for the structure functions at small $x$ and derive a general form of their small-$x$ asymptotics, demonstrating that there is no room for Eq. (2) at $x \to 0$. In Section 5 we discuss the role of singular factors conventionally used in DGLAP-fits for initial parton distributions. We consider the structure functions at small $Q^2$ in Section 6. Finally, Section 7 is for our concluding remarks.

2. GENERAL STRUCTURE OF THE DIS STRUCTURE FUNCTIONS

All DIS structure functions are given by a convolution of perturbative components $f_r^{pert}$ and parton distributions $r$. For instance, in collinear factorization and when DGLAP is used, the non-singlet structure function $f_{NS}(x, Q^2)$ is represented as the convolution

$$f_{NS}(x, Q^2) = C_q(x, x_0) \otimes \Delta q(x_0, Q^2),$$

where $C_q$ is the quark coefficient function and $\Delta q(x_0, Q^2)$ stands for the quark evolved distribution defined at scale $Q^2$. $C_q(x, x_0)$ controls evolution of this distribution from $x_0$ to $x$. The $Q^2$-evolution of the quark distribution from the initial scale $\mu^2$ to scale $Q^2$ is controlled by the DGLAP evolution equations [1]. It can be written as

$$\Delta q(x_0, Q^2) = E(Q^2, \mu^2) \otimes \Delta q(x_0, \mu^2),$$

where the initial quark distribution $\Delta q(x_0, \mu^2)$ is conventionally chosen at $x_0 \sim 1$ and $\mu \sim 1$ GeV. The scale $\mu^2$ is called the factorization scale. Equations (3), (4) can be written as one convolution:

$$f_{NS}(x, Q^2) = [C_q(x, y) \otimes E(Q^2, \mu^2)] \otimes \Delta q(\mu^2),$$

where $f_{NS}^{pert}(x, Q^2) = f_r^{pert}(q, Q^2, \kappa^2) \otimes \Phi_r(p, \kappa^2),$ (6)

where $\Phi$ denotes parton distributions in any of the factorizations, the subscript $r$ marks the intermediate partons (quarks and gluons) with momentum $\kappa$ and the summation over $r$ takes place when necessary. The notation $\otimes$ means the one-dimensional integration over the longitudinal for collinear factorization and two-dimensional (both the longitudinal and transverse momenta) in the case of $k_T$-factorization; $\kappa^2 = \mu^2$ in the case of collinear factorization. In Eq. (6) we have dropped a possible dependence on unessential variables like the target spin and mass.

2.1. General Structure of the Perturbative Component

The simplest form of structure functions corresponds to collinear factorization where it can be written in terms the Mellin integral:

$$f = \int \frac{d\omega}{2\pi_i} \omega^{s-1} f^{pert}(\omega) \delta q(\omega) + f^{pert}_g(\omega) \delta g(\omega),$$

with $\delta g$ and $\delta g(\omega)$ standing for the quark and gluon distributions in the $\omega$-space respectively. In Eq. (7) they are convoluted with the perturbative contributions $f_r^{pert}$. These perturbative contributions in any factorization have the following generic structure:

$$f_r^{pert} = \int \frac{d\omega}{2\pi_i} \omega^{s-1} C_r(\omega, \alpha_s, \mu^2) \tilde{\Omega}_r(\omega, \alpha_s, Q^2, \kappa^2),$$

where the term $C_r$ is a generic notation for the coefficient functions and $\tilde{\Omega}$ is expressed through the matrix of anomalous dimensions. For instance in LO DGLAP, where, in collinear factorization, $\kappa^2 = \mu^2$, the non-singlet perturbative component $f_{NS}^{pert}(\omega) \equiv f^{pert}_q(\omega)$ is expressed in terms of the non-singlet coefficient function $C_{NS}$ and $\tilde{\Omega}_{NS}$:

$$C_{NS}^{(LO)} = 1, \quad \tilde{\Omega}_{NS}^{(LO)} = \gamma_{qq}^{(0)}(\omega) \int \frac{dk_+^2}{\mu^2} \frac{\alpha_s(k_+^2)}{\ln(k_+^2)},$$

with $\gamma_{qq}^{(0)}(\omega)$ being the well-known quark-quark anomalous dimension and $b = (33 - 2n_f)/(12\pi)$. In NLO DGLAP, both $C_{NS}$ and $\Omega_{NS}$ acquire additional terms proportional to $\alpha_s$. In particular, the structure of the NLO coefficient functions is

$$C_{NS}^{(NLO)} = 1 + \alpha_s(Q^2) \tilde{C}_{NS}(\omega).$$

We have used this simple example in order to demonstrate explicitly that the $Q^2$-dependence of any structure function $f$ is achieved through the $Q^2$-dependence of its perturbative components $f_r^{pert}$. The $Q^2$-dependence of $f_r^{pert}$ comes from the upper limit $Q^2$ of integrations over $k_+^2$ in expressions for both $\Omega_r$, as explicitly shown in Eq. (9), and in expressions for
coefficient functions. The latter is related to the parametrization $\alpha_s = \alpha_s(Q^2)$. This feature is common for all structure functions, although specific expressions for $C_{rr}$ and $\Omega r r'$ are different for different structure functions.

3. $Q^2$-DEPENDENCE OF THE QCD COUPLING

In this section we discuss parametrizations of $\alpha_s$ in DGLAP equations in collinear factorization at different values of $x$ and $\mu^2$. Although for the sake of simplicity we consider the LO DGLAP equations, our conclusions are valid for NLO, NNLO and so on. In the LO DGLAP evolution equation the parametrization (1) appears when the integral DGLAP equations for $f_r^{(\text{pert})}$

$$f_r^{(\text{pert})}(x, Q^2) = \int \frac{dk_2^2}{k_2^2} \int \frac{d\beta}{\beta} \alpha(x, Q^2) P_{rr}(\beta)$$

(11)

$$\times \left(\frac{x}{\beta}, Q^2/k_2^2\right)$$

are reduced to the differential equations

$$\frac{\partial f_r^{(\text{pert})}(x, Q^2)}{\partial \ln Q^2} = \alpha(Q^2) \int \frac{d\beta}{\beta} f_r^{(\text{pert})}(x, Q^2, \beta) P_{rr}(\beta).$$

(12)

Equations (11), (12) demonstrates explicitly that Eq. (1) holds when (i) the upper limit of integration over $k_2^2$ in Eqs. (11) is $Q^2$ which corresponds to $x \sim 1$, (ii) the parametrization

$$\alpha_s = \alpha_s(k_2^2)$$

(13)

is used in the involved Feynman graphs. Throughout the present paper we will refer to the parametrization of Eq. (13) as the standard parametrization. According to the results of [8], one can use the standard parametrization (13) in expressions for $f_r^{(\text{pert})}$ in collinear factorization only when the following two conditions are fulfilled: First, values of $x$ should be large:

$$x \sim 1,$$

(14)

to ensure the use of $Q^2$ instead of $2pq$. Second, the factorization point $\mu^2$ should obey the strong inequality

$$\mu \gg e^{-\pi} \Lambda^2 \approx 23 \Lambda^2.$$  

(15)

When one of both of the requirements in Eqs. (14), (15) are violated, the coupling $\alpha_s(k_2^2)$ in the integral DGLAP evolutions equations for $f_r^{(\text{pert})}$, should be replaced by the effective coupling $\alpha_{\text{eff}}$, as shown in [8]. This coupling can be represented by different approximative expressions, depending on the kinematics. In Subsections A and B we consider the cases of violating either (14) or (15) and consider violation of both of them in Subsection C.

3.1. Case A

When Eq. (15) is violated but $x$ is so close to 1 that essential $\beta$ in Eq. (11) are $\sim 1$, the coupling $\alpha_s(k_2^2)$ in Eq. (11) should be replaced by

$$\alpha_{\text{eff}}(k_2^2) = \frac{1}{b(i_0 + \pi^2)} - \frac{1}{\pi b} \arctan\left(\frac{\pi}{l_0}\right)$$

$$+ \frac{1}{\pi b} \arctan\left(\frac{\pi}{l(\beta)}\right),$$

(16)

where we have denoted

$$l_0 = \ln(\mu^2/\Lambda^2), \quad \tilde{l}(k_2^2) = \ln(k_2^2/\Lambda^2).$$

(17)

It leads to replacement of the integration of $\alpha_s(k_2^2)$ in Eq. (9) by the integration of $\alpha_{\text{eff}}(k_2^2)$ over the same interval:

$$\int \frac{d\beta}{\beta} \alpha_s(k_2^2) \to \int \frac{d\beta}{\beta} \alpha_{\text{eff}}(k_2^2).$$

(18)

Let us notice that when $\mu$ obeys Eq. (15), the first and second terms in Eq. (16) cancel each other while the third term can be approximated by $\alpha_s(k_2^2)$. This reduces the integral in Eq. (18) to the DGLAP expression in Eq. (9).

3.2. Case B

Let us consider the opposite situation when $\mu$ satisfies Eq. (15) but $x$ is small. In this case $\alpha_s(k_2^2)$ in Eq. (11) should be replaced by $\alpha_s(k_2^2)/\beta$ and the upper limit of integration over $k_2^2$ should be changed. The point is that integration over $k_2^2$ always runs from some starting point $\mu^2$ (which is fixed from physical considerations and sometimes coincides the factorization scale) to the total invariant energy

$$s = (p + q)^2 \approx w(1 - x),$$

(19)

with $w = 2pq$. In the DGLAP framework, where $x$ is not far from 1, $s \approx Q^2$, so in the DGLAP Eq. (11) the upper limit is $Q^2$. On the other hand, $s \approx w$ at small $x$. This leads to replacement of Eq. (11) by the following equation:

$$f_r^{(\text{pert})}(x, Q^2) = \int \frac{d\beta}{\beta} \alpha_s(k_2^2) \left(\frac{x}{\beta}\right)$$

$$\times \left(\frac{x}{\beta}, Q^2/k_2^2\right) P_{rr}(\beta).$$

(20)
Relations were constructed for approaches (see e.g. [11, 12]) where the Dispersion amplitudes. This approach is similar to the discussion it briefly in the next section. To conclude, we used only in the context of evolution equations. A more general treatment of the QCD coupling, where only logarithms of $Q^2$ are resummed. A generalization of the DGLAP equations to the small-$x$ region was done in [13] (see also overview [14]) for the spin structure function $g_1$ and non-singlet component of $F_1$; there were resummed the leading, double logarithms of both $x$ and $Q^2$ and at the same time the QCD coupling in each rung of the involved Feynman graphs was running. Applying the saddle-point method to the structure functions obtained in [13] exhibited their Regge behavior at $x \to 0$, with the intercepts being just numbers without any parameters (e.g. $\alpha_s$, etc.). The intercept of the non-singlet $F_1$ proved to be 0.38, the intercept of the non-singlet $g_1$ was 0.42 and the intercept of the singlet $g_1$ was 0.86.

3.3. Case C

Finally, when $\mu$ does not satisfy Eq. (15) and, in addition, $x \ll 1$, the coupling $\alpha_s(k^2_\perp/\beta)$ in Eq. (20) should be replaced by $\alpha_{seff}(k^2_\perp/\beta)$:

$$\alpha_{seff}(k^2_\perp/\beta) = \frac{1}{\beta} \frac{d}{\beta} \frac{l_0}{b(l_0^2 + \pi^2)} - \frac{1}{\pi b} \arctan \left( \frac{\pi}{l_0} \right)$$

$$+ \frac{1}{\pi b} \arctan \left( \frac{\pi}{l} \right), \quad (22)$$

with $l = \ln(k^2_\perp/(\beta A^2))$. It converts Eq. (20) into a new equation:

$$f_r^{\text{pert}}(x, Q^2) = \int_{\mu^2}^{\omega(\mu)} \int_{k^2_\perp/b}^{\infty} d^2 F_s(\omega(\mu), \rho), \quad (23)$$

Equations (20), (23) explicitly demonstrate that there is no factorization between the integrations over $\beta$ and $k^2_\perp$ at small $x$. In other words, the factorization between the longitudinal and transverse spaces taking place in DGLAP vanish in the small-$x$ kinematics. Equations (20), (23) also show that structure functions at small $x$ depend on $Q^2$ through the integration limit $\beta_0$ while the effective couplings at $x \ll 1$ differ a lot from the standard parametrization given by Eq. (1). Equation (23) corresponds to the case when both Eqs. (14) and (15) are violated while the expressions for the couplings and structure functions in Subsections A and B correspond to violation of either Eqs. (14) or (15) and can easily be obtained from Eqs. (22), (23). Nevertheless, we accentuate that Eq. (23) is also approximation obtained in [8] in order to factorize the coupling. This expression should be used only in the context of evolution equations. A more general treatment of the QCD coupling, where the factorization was not required, was done in [9]. We discuss it briefly in the next section. To conclude, we would like to notice that Eq. (23) was obtained with constructing Dispersion Relations for forward scattering amplitudes. This approach is similar to the approach of Ref. [10] but differs from the alternative approaches (see e.g. [11, 12]) where the Dispersion Relations were constructed for $\alpha_s$ by itself.

Obviously, logarithms of $x$ are large in the small-$x$ region, so their re-summation to all orders in $\alpha_s$ is important. This is beyond of the reach of DGLAP, where only logarithms of $Q^2$ are resummed. A generalization of the DGLAP equations to the small-$x$ region was done in [13] (see also overview [14]) for the spin structure function $g_1$ and non-singlet component of $F_1$; there were resummed the leading, double logarithms of both $x$ and $Q^2$ and at the same time the QCD coupling in each rung of the involved Feynman graphs was running. Applying the saddle-point method to the structure functions obtained in [13] exhibited their Regge behavior at $x \to 0$, with the intercepts being just numbers without any parameters (e.g. $\alpha_s$, etc.). The intercept of the non-singlet $F_1$ proved to be 0.38, the intercept of the non-singlet $g_1$ was 0.42 and the intercept of the singlet $g_1$ was 0.86.

4. GENERAL STRUCTURE OF THE EVOLUTION EQUATIONS FOR DIS STRUCTURE FUNCTIONS

In this section we, consider general expressions for the structure functions, skipping unessential details. Throughout the present section we imply that collinear factorization is used, though a generalization to $k_T$-factorization is easy to do. As equations for the structure functions involve convolutions (see e.g. Eq. (5)), it is convenient to represent the perturbative contribution $f_r^{\text{pert}}(x)$ in terms of the Mellin transform:

$$f_r^{\text{pert}}(x) = \int_{-1}\frac{d\omega}{2\pi} x^{-\omega} F_r(\omega, y), \quad (24)$$

were we have denoted $y = \ln(Q^2/\mu^2)$ and introduced the Mellin amplitude $F_r$. Focusing on the $t$-channel intermediate state with two partons and neglecting other contributions (see for detail [14]) allows us to compose the following system of equations for $F_r$:

$$[\omega + \partial/\partial y] F_r(\omega, y) = F_r(\omega, y) H_r(\omega). \quad (25)$$

Solving these equations, we arrive at

$$f(x, Q^2) = \sum_{r=1}^{\infty} \int_{-\infty}^{\infty} d\omega \frac{d\omega}{2\pi t} x^{-\omega} F_r(\omega, y) \delta r(\omega)$$

$$= \sum_{r=1}^{\infty} \int_{-\infty}^{\infty} d\omega \frac{d\omega}{2\pi t} C_r(\omega) e^{\Omega_r(\omega)} \delta r(\omega), \quad (26)$$

where $r = q, g$, so that $\delta r = \delta g, \delta g$, and $\Omega_r$ is made of new matrix of anomalous dimensions $H_r$. Both $C_r$ and $H_r$ account for both the total resummation of logarithms of $x$ and running $\alpha_s$ effects. As $\alpha_s$ depends on the longitudinal Sudakov variables, it participate in the
Mellin transform (see [9] for detail). As a result, \(\alpha_s\) with the time-like argument is replaced by

\[ A(\omega) = \frac{1}{b} \left[ \frac{\eta - \omega}{1 + \pi^2} \right] e^{i\eta^2} \int_0^\infty d\rho \frac{e^{-i\rho}}{(\rho + \eta)^2 + \pi^2}, \]  

(27)

where \(\eta = \ln(\mu^2/\Lambda_{QCD}^2)\) and \(\mu\) is the IR cut-off. When the argument of the coupling is space-like, the \(\pi^2\)-terms are absent.

Comparison of Eqs. (26) and (8) shows that the coefficient functions \(C_i\) do not depend on \(Q^2\) at all. The \(Q^2\)-dependence of \(f_\sigma(x, Q^2)\) is located in the exponent of (26) and it is controlled by the anomalous dimensions. The small-\(x\) asymptotics of \(f_\sigma\) can be obtained with applying the saddle-point method to Eq. (26). The stationary phase is obtained as a solution to the following equation:

\[ \frac{d}{d\omega} [\omega \xi + \ln C_y(\omega) + y \Omega_x(\omega)] = \xi + \frac{1}{C_y} \frac{dC_y}{d\omega} + y \frac{d\Omega_x}{d\omega} = 0, \]

where \(\xi = \ln(1/x)\). This equation should be solved at \(\xi \to \infty\) and fixed \(y\) and the solution, \(\omega_0\), is called the stationary point. The rightmost root of Eq. (28) stipulates the small-\(x\) asymptotic behavior of \(f_\sigma\), with

\[ \Delta = \max[\omega_0], \]

(29)

being the intercept of the structure function. Equation (28) implies that the large factor \(\xi\) must be equated by another large factor. As \(y\) is fixed, such a factor can be any of the following options:

(i) \(C_y(\omega) \to -0\),

(30)

(ii) \(dC_y(\omega)/d\omega \to \infty\),

(31)

(iii) \(d\Omega_x(\omega)/d\omega \to \infty\),

(32)

when \(\omega \to \omega_0\). Accounting for logarithmic contributions \(-\ln x\) to \(C_y(\omega)\) and \(\Omega_x\), means that they acquire contributions \(-c_a/\omega^{1+n}\) and \(-c_a/\omega^n\) respectively and therefore any of them and \(dC_y/d\omega\), which is \(-c_a/\omega^{2+n}\), are singular at \(\omega \to \omega_0 = 0\). Obviously, fulfilment of Eq. (30) can be achieved only when a part of \(c_a\) is negative, which contradicts to calculations made in DGLAP and to expressions for the non-singlet structure functions obtained in [13]. Then, let us note that as contributions to \(dC_y/d\omega\) are more singular than contributions to \(C_y\) or \(\Omega_x\), the case (ii) is the most important compared to (i) and (iii). Indeed, \(\omega\) should be small in order to prevent oscillations of the factor \(\exp(\xi\omega)\) in Eq. (26) at large \(\xi\). The series of the pole contributions \(-1/\omega^a\) can be summed up. For example, the coefficient function \(C_{NS}\) and anomalous dimension \(H_{NS}\) for the non-singlet structure function \(F_1^{NS}\) (for this case \(\Omega_\omega(\omega)\) is replaced by \(H_{NS}(\omega)\)) proved to be

\[ C_{NS} = \frac{\omega}{\omega - H_{NS}}, \]

\[ H_{NS} = (1/2)[\omega - \sqrt{\omega^2 - B_{NS}(\omega)}]. \]

When \(\omega\) is fixed, \(B_{NS} = 2\omega C_\omega/\pi\), otherwise it is given by a much more complicated expression (see [13] for detail). It is easy to see that all coefficients in the expansion of \(C_{NS}\) into series in \(1/\omega^a\) are positive. This also excludes Eq. (30) and demonstrates that Eq. (31) corresponds to the most important case. So, we arrive at the asymptotics of \(f_\sigma\) in the form of following contributions of the Regge type: at \(x \to 0\)

\[ f(x, Q^2) \sim x^{-\Delta}(Q^2/\mu^2)^{\Omega(\lambda)} x^\delta r. \]

Equations (26), (34) demonstrate explicitly that the dependence of the structure functions on \(Q^2\) has nothing to do with the \(Q^2\)-dependence of the coupling.

5. REMARK ON THE DGLAP-FITS FOR STRUCTURE FUNCTIONS

The asymptotics (34) is of the Regge type. The Regge behavior is generated by total resummations of leading logarithms of \(x\) and it is unrelated to behavior of the initial parton densities \(\delta f(x)\) and \(\delta g(x)\). In particular, both \(\delta f(x)\) and \(\delta g(x)\) are not supposed to reveal a power behavior \(-x^{-a}\) at small \(x\). On the contrary, the standard DGLAP fits

\[ \delta q, \delta g = N x^{-a}(1-x)^b (1+c x)^d, \]

(35)

with \(a, b, c, d, N > 0\), conventionally includes such factors. The singular factors \(x^{-a}\) are incorporated in the fits ad hoc in order to provide \(f_\sigma\) with a steep growth at small \(x\) and thereby meet experimental data. Indeed, in the \(\omega\)-space the factor \(x^{-a}\) corresponds to the pole contribution

\[ \delta q_p = 1/(\omega - a). \]

(36)

Being installed in Eq. (7), the pole contribution (36) straightforwardly leads to the Regge asymptotics

\[ f \sim x^{-\Delta} \left[ \frac{\ln(Q^2/\Lambda^2)}{\ln(\mu^2/\Lambda^2)} \right]^{\Omega(\lambda)/b}, \]

(37)

which differs a lot from both Eq. (34) and the well-known LO DGLAP-asymptotics

\[ f \sim \exp \left[ \frac{C}{2\pi b} \ln(1/x) \ln \left( \frac{\ln(Q^2/\Lambda^2)}{\ln(\mu^2/\Lambda^2)} \right) \right]. \]

(38)
Let us note that Eqs. (34), (38) involve non-singular fits. Confronting (34) to (37) proves that the only role of the singular factors $x^{-a}$ is, actually, to mimic the total resummation of $\ln^a x$. When the resummation is accounted for, these factors can be dropped and therefore the number of parameters in the fits can be reduced. The qualitative difference between the asymptotics (34) and (37) includes two items:

(i) The intercept $\Delta$ in Eq. (34) is calculated while $a$ in (37) is fixed from experiment.

(ii) The factor $x^{-a}$ in Eq. (34) is present in the asymptotic expressions, i.e. at $x \rightarrow 0$, only. It never appears in expressions for the structure functions like Eq. (7) at finite $x$. On the contrary as soon as the fit (35) is used, the factor $x^{-a}$ is present in Eq. (7) at any $x$, including large $x \sim 1$. It means that, in a sense, the $x$-dependence of $f$ is always controlled by its asymptotics, when singular fits are used. This contradicts to the observation made in [17]: the small-$x$ asymptotics represent the structure functions reliably at very small $x$ ($x < 10^{-8}$) only while at $x > 10^{-8}$ the structure function is much greater than its asymptotics. The latter leads to the quantitative difference between $a$ and $\Delta$. In order to force Eq. (37) to represent $f$ at presently available $x$, i.e. at $x > 10^{-8}$, one has to increase $a$, which leads to the following relation:

$$a > \Delta. \quad (39)$$

By this reason, we will name the fictitious intercepts $a$ as pseudo-intercepts. As their values are determined from experiment at available $x$, they always exceed genuine intercepts. So, the situation looks like that: On one hand, the use of the pseudo-intercepts $a$ allows one to approximate Eq. (7) by its asymptotics which is given by simple Regge-like expressions (37). On the other hand, the power $x$-dependence in Eq. (37) has nothing to do with impact of genuine Reggeons introduced in Theory of the Regge poles. The wide-spread tactics to use pseudo-Reggeons, instead of resummation of $\ln x$, in order to solve immediate practical tasks leads to serious theoretical problems especially important for the singlet structure function $F_1$ and the singlet parton distributions: there are no available expressions for those objects besides their Regge asymptotics $x^{-\Delta_P}$, with $\Delta_P$ being the Pomeron intercept. In order to fit such asymptotics to explanation of experimental data at available energies, they use one or several Pomerons with large pseudo-intercepts $\Delta_P$ violating the Froissart bound. Finally, let us note that necessity to include singular factors in the fits is a clear indication that essential logarithms of $x$ are not accounted for.

6. STRUCTURE FUNCTIONS AT SMALL $Q^2$

Description of the structure functions at small $Q^2$ is important because this kinematics has been investigated experimentally. For instance, the spin-dependent structure functions at small $Q^2$ are investigated by the COMPASS Collaboration (see e.g. [15]). On the other hand, this region is absolutely beyond the reach of DGLAP. Despite this, sometimes in the literature (see e.g. [2, 3], recent paper [5] and refs therein) the DGLAP-parametrization $\alpha_s(Q^2)$ is used, the factor (35) is present in the fits. Confronting (34) to (37) proves that the only role of the singular factors in the fits is a clear indication that $\alpha_s(Q^2)$ should be replaced by the effective coupling $\alpha_{\text{eff}}$. The coupling $\alpha_{\text{eff}}$ does not depend on $Q^2$ at small $Q^2$ or at small $x$, so $\alpha_s(Q^2)$ should be replaced by the effective coupling $\alpha_{\text{eff}}$. The coupling $\alpha_{\text{eff}}$ does not depend on $Q^2$ at small $Q^2$ or at small $x$, which makes the shift (40) absolutely unnecessary. Let us stress that interpretation of the approximation $\alpha_s(Q^2)$ and the shift (40) as exact expressions has led to various misconceptions abundant in the literature. On the other hand, the small-$Q^2$ kinematics has been investigated experimentally by the COMPASS Collaboration (see e.g. [15]), so it is important to describe the structure functions in this region. In [16] we proved that the expressions in [13] for the structure function $g_1$ at small $x$ and large $Q^2$ can be extended to small $Q^2$ by shifting

$$k_1^2 \rightarrow k_1^2 + \mu^2, \quad (41)$$

in propagators of the soft quarks and gluons. The shift (41), where $\mu$ is a cut-off, is necessary to regulate infrared singularities in involved Feynman graphs. This shift eventually leads to the shift

$$Q^2 \rightarrow Q^2 + \mu^2, \quad (42)$$

in logarithmic contributions to the structure functions. Our estimate for $\mu$ obtained with using Principle of Minimal Sensitivity [18] was $\mu \approx 1$ GeV. The shift (42) can be neglected at $Q^2 \gg \mu^2$ but becomes essential at small $Q^2$, making possible description of the kinematic region where $Q^2$ are small. For example, DIS at such a kinematics has been studied experimentally by the COMPASS collaboration. Therefore, it is the shift (41) that brings theoretical grounds for description of the small $Q^2$-region. Let us stress that this shift should not been applied to $\alpha_s$ and it has nothing to do with the baseless modification (40) of the coupling.

It is interesting to notice that the shift (40) can be used to clarify the problem of higher twists and, in addition, it explains the puzzle of the power $Q^2$-corrections. A namely, the contributions $\sim 1/(Q^2)^a$ to DIS structure functions, usually attributed to higher twists,
are known to be present at large $Q^2$ but enigmatically disappear at small $Q^2$ where they could be extremely impactive. A simple and natural solution of this puzzle was found in [16] (see also overview [14]). In brief, it can be reduced to the following: Among different contributions to the structure functions, there are contributions

$$T_n \sim \ln ^n ((Q^2 + \mu^2)/\mu^2). \quad (43)$$

In the region of large $Q^2$, where $Q^2 > \mu^2$, such contributions can be expanded into power series in the following way:

$$T_n \sim \ln ^n (Q^2 + \mu^2) + \sum \left( \frac{\mu^2}{Q^2} \right)^k. \quad (44)$$

The logarithmic term in Eq. (44) is included into the leading twist contributions whereas the power terms are identical to the power terms attributed to higher twists. Such terms are conventionally supposed to have non-perturbative origin. However, Eq. (44) explicitly demonstrates that there are the power terms of purely perturbative nature. Surely, they should be accounted for in the first time and only the rest should be attributed to higher twists.

On the other hand, the expansion (44) holds at large $Q^2$ only. In the small-$Q^2$ region the power expansion of Eq. (43) looks different:

$$T_n \sim 1 + \sum \left( \frac{\mu^2}{Q^2} \right)^k. \quad (45)$$

The first term in the r.h.s. of Eq. (45) is included into the leading twist contributions while the other terms are again the power-$Q^2$ corrections, though with $Q^2$ in the nominator. Equation (45) proves that the power corrections $\sim 1/(Q^2)^n$ can never become singular at small $Q^2$. Comparing Eq. (44) to (45) reveals that the corrections $\sim 1/(Q^2)^n$ are about vanishing at

$$Q^2 \sim \mu^2, \quad (46)$$

where none of expansions (44), (45) can be used. As we have mentioned, we fixed using the Principle of Minimal Sensitivity [18] and arrived at $\mu \approx 1$ GeV for the non-singlet contributions to the structure functions $F_L$ and $g_1$. Our prediction of vanishing power corrections $\sim 1/(Q^2)^n$ at $Q^2$ approaching 1 GeV² perfectly agrees with estimates obtained by analysis of experimental data.

To conclude this section, we would like to add an important remark: the shift (42) together with the parametrization $\alpha^* = \alpha_s(k^2_\perp)$ and the shift

$$\alpha_s(k^2_\perp) \longrightarrow \alpha_s(k^2_\perp + \mu^2), \quad (47)$$

undoubtedly are correct when $k$ denote moments of soft gluons propagating in the $t$ channel and connecting quarks. In this case $\mu$ should be introduced as an infrared cut-off, so in the limit of small $k^2_\perp$, $\alpha_s$ tends to its frozen value $\alpha_s(\mu^2)$. In [16] we found that $\mu \approx 1$ Gev for the non-singlet structure functions $g_1^{NS}$, $F_T^{NS}$. The same value of $\mu$ can be used for other cases with non-vacuum quantum numbers in the $t$-channel.

7. CONCLUSIONS

In the present paper we have analyzed the $Q^2$-dependence of the structure functions, considering separately this dependence in the kinematic region of large and small $x$. Our consideration embraced both large and small values of $Q^2$. We argued against the conventional point of view that the $Q^2$-dependence at any $Q^2$ and $x$ is originated by the DGLAP-parametrization $\alpha_s = \alpha_s(Q^2)$ leading to $Q^2$-dependence of the intercepts of the structure functions. We showed that this parametrization holds exceptionally in the region of large $x$ and $Q^2$, providing that in this region the factorization scale should be large. Outside this region, $\alpha_s$ should be replaced by the effective coupling $\alpha_{eff}$. At small $x$, coupling $\alpha_{eff}$ depends on both transverse and longitudinal momenta, which destroys the factorization of the phase space into the longitudinal and transverse spaces taking place in DGLAP. In addition, the integration limits do not involve $Q^2$. As a result, the effective coupling does not depend on $Q^2$ in the small-$x$ region. This leads to the Regge small-$x$ asymptotics of the structure functions, with intercepts independent of $Q^2$. We also argued against the shift $\alpha_s(Q^2) \longrightarrow \alpha_s(Q^2 + \mu^2)$ used in the literature to keep $\alpha_s$ in perturbative domain at small $Q^2$. In this regard, we reminded that the parametrization $\alpha_s(Q^2)$ as well as DGLAP in whole should be used at large $Q^2$ only. Superficial use of the shift $\alpha_s(Q^2) \longrightarrow \alpha_s(Q^2 + \mu^2)$ at small $Q^2$ has led to various misconceptions known in the literature. In contrast, we advocated the use of shift $Q^2 \longrightarrow Q^2 + \mu^2$ in such evolution equations, derivation of which is not based on assuming $Q^2$ large. We stressed that the shift did not involve parametrization of the QCD coupling. Eventually, we have considered theoretical grounds for such a shift and discussed its application to the power $Q^2$-contributions to the structure functions.
