In the framework of population dynamics, the basic reproduction number $R_0$ is, by definition, the expected number of offspring that an individual has during its lifetime. In constant and time periodic environments, it is calculated as the spectral radius of the so-called next-generation operator. In continuously structured populations defined in a Banach lattice $X$ with concentrated states at birth, one cannot define the next-generation operator in $X$. In the present paper, we present an approach to compute the basic reproduction number of such models as the limit of the basic reproduction number of a sequence of models for which $R_0$ can be computed as the spectral radius of the next-generation operator.

We apply these results to some examples: the (classical) size-dependent model, a size-structured cell population model, a size-structured model with diffusion in structure space (under some particular assumptions), and a (physiological) age-structured model with diffusion in structure space.

1 | INTRODUCTION

In a deterministic model of population growth, the basic reproduction number $R_0$ is defined as the expected number of offspring that an individual has throughout his life (in an epidemiological model, as the expected number of new infections a newly infected individual will produce). The main interest of the basic reproduction number is that, as it is intuitively clear, a small population will (begin to) establish in a given environment if $R_0 > 1$, whereas it will become extinct whenever $R_0 < 1$. Similarly, provided some infected individual is present, an epidemic outbreak will arise if $R_0 > 1$, whereas the opposite strict inequality guarantees that the epidemic will not occur.

In structured populations, when the birth event can happen in different individual states (of size, phenotype, spatial position, etc.) one talks of “typical” individual, but it is not always clear what “typical” individual means and so which is the expected number of offspring of a “typical” individual.

On the other hand, in deterministic modeling, one could be concerned with a definition that involves a probability concept as expectation and would like to have a deterministic definition as well.

Both drawbacks are solved by defining $R_0$ as the spectral radius of the so-called next-generation operator, which maps a (distribution of) population to the (distribution of) population of their offspring along the whole life span of the former.$^{1-4}$
Nevertheless, in some models, the definition of the birth operator and that of the next-generator operator depend on the choice of the sometimes arbitrary concept of birth event.\textsuperscript{5,6} Hence, more than one basic reproduction number can be meaningfully defined in some models.\textsuperscript{5,6}

When the population dynamics can be described by a linear system of ODEs, the next-generation operator is a matrix for which the spectral radius can be computed, and therefore, there is no problem with the definition above leaving apart that it may be nonuniquely determined, as commented in the previous paragraph. Fortunately (we should better say inevitably), the sign of $R_0$ coincides with that of the real part of the so-called Malthus constant (the first eigenvalue of the matrix defining the system of ODEs), independently of the choice of the decomposition of the latter in a mortality/transition operator and a birth operator provided some natural assumptions hold.\textsuperscript{1,5} The sign relation also holds in infinite dimension.\textsuperscript{3}

However, in continuously structured populations with concentrated state at birth, the birth rate shows as a boundary condition instead of a birth operator. This makes it difficult (or impossible) to obtain the next-generation operator and thus adapt to these type of models in infinite dimensional spaces (which we will call type II models) the above definition of $R_0$. In order to overcome this difficulty, in the present paper, we consider some examples where $R_0$ is defined for type II models as a limit of basic reproduction numbers of approximate models with distributed states at births for which the next-generation operator can be defined as a bounded linear operator, which we call type I models.

More explicitly, we will consider diffusion–convection partial differential equations of the form of conservation laws for the density of individuals with respect to some one-dimensional continuous variable, which stands for a physiological state as size or age or for an external state as spatial position, with nonflux boundary conditions and with an incoming flow of new individuals via a birth operator whose range is the span of a function in the space of states giving the distribution of the offspring (for which the next-generation operator is well defined).

Next, we will assume a sequence of type I models such that this distribution of offspring concentrates at some point in the closure of the domain of the structuring variable. This sequence tends to a conservation law where the birth term appears as a boundary condition and consequently the next-generation operator is not definable as a bounded linear operator in the state space. Many of the classic age and size-structured population models are of this second class, which we call type II models. For this, we define its basic reproduction number as the limit (it exists uniquely under suitable hypotheses) of the basic reproduction numbers of the sequence of type I models tending to it.

A different approach to overcome the difficulty to define the next-generation operator in the case of concentrated states at birth is to consider the space of measures as state space. This is done for discrete-time population dynamics in the recent reference.\textsuperscript{7}

The paper is organized as follows: in Section 2, we give, in a general framework, the definition of $R_0$ for type II models as the limit of the sequence of basic reproduction numbers of type I models given by conservation laws for the density of individuals with respect to some one-dimensional continuous variable. Section 3 is devoted to the application of the results in Section 2 to some examples: the (classical) size-dependent model, a size-structured cell population model, a size-structured model with diffusion in structure space (under some particular assumptions), and a (physiological) age-structured model with diffusion in structure space. For this last example, the computation of the basic reproduction number for the sequence of type I models is done in two different ways, one of them included in the Appendix. At the end of Section 3, a brief discussion on the dependence of $R_0$ on the diffusion coefficient is undertaken with the conclusion that, for some age-specific birth functions, there is an optimal value of the diffusion coefficient, which maximizes $R_0$. Therefore, the presence of a moderate diffusion in age tends to increase $R_0$ and hence the survival chances of a population.

## 2 | GENERAL FRAMEWORK

Some models in population dynamics (which we call type I models, see Barril et al\textsuperscript{6}) can be described by nonlinear abstract differential equations for the density of individuals with respect to some structuring variables. Specifically, let $X$ be a Banach lattice, and let $u(t) \in X$ be the distribution of individuals at time $t \geq 0$, and then the original nonlinear ecological problem can be decomposed as

$$u'(t) = B(u(t))u(t) - M(u(t))u(t), \quad u(0) = u_0 \in X,$$

where for any $u$, $B(u)$ is the linear birth operator; and for any $u$, $M(u)$ is the linear operator corresponding to nonbirth terms (mortality and transitions in general). Of course, as mentioned before, this decomposition depends on what is considered
as a birth event.\textsuperscript{5,8} For the study of possible extinction or settlement of the population, we can focus on the so-called extinction steady-state \( u^* = 0 \) and its stability, which is analyzed by means of the following formal linearized model:

\[
u'(t) = Bu(t) - Mu(t) , \ u(0) = u_0 \in X .
\]

where we set \( B := B(0) \) and \( M := M(0) \) with some abuse of notation.

In order to proceed, we need the following assumptions: \( B : D_B \subset X \to X \) is a positive linear operator, and \( M : D_M \subset X \to X \) is such that \( -M \) is the generator of a strongly continuous semigroup of positive linear operators \( T(t) := e^{-Mt} \), whose spectral bound is strictly negative \( s(-M) < 0 \) (so that the population goes to extinction when there are no births). Therefore, 0 belongs to the resolvent set of \( M \), and there exists \( \int_0^\infty T(t) \, dt = M^{-1} \). Moreover, we assume that \( D_M \subset D_B \) and that the linear operator \( BM^{-1} \) is bounded. That is guaranteed, for instance, when \( B \) is bounded, but this is not a necessary condition (see Barril et al.\textsuperscript{8} Sect. 5). Finally, we assume that \( B - M \) is the infinitesimal generator of a positive semigroup.

The operator \( BM^{-1} \) can be interpreted as the next-generation operator. For the finite dimensional case, see, for instance, Cushing and Diekmann.\textsuperscript{5} In the infinite dimensional case, if \( B \) is bounded, see Diekmann et al\textsuperscript{3} and Section 3 in Barril et al.\textsuperscript{8} If \( B \) is not bounded, \( BM^{-1} \) is still interpreted as the next-generation operator; see Thieme\textsuperscript{2} and Section 5 in Barril et al.\textsuperscript{8}

For type I models, we have that the next-generation operator \( BM^{-1} \) is defined on the same Banach space \( X \) as the population density. The basic reproduction number \( R_0 \) (which is an alternative to the Malthusian parameter) is then given by the spectral radius of the positive bounded linear operator \( BM^{-1} \).\textsuperscript{3,8} Moreover, \( R_0 \) is a nonnegative spectral value, which is actually the largest \( \lambda \geq 0 \) for which the operator \( B - \lambda M \) does not have a bounded inverse; see, e.g., Barril et al.\textsuperscript{6}

Often, \( R_0 \) cannot be computed explicitly, and then the following upper bound is useful to find a sufficient condition for extinction:

\[
R_0 \leq \|BM^{-1}\|_X = \sup \left\{ \frac{\|BM^{-1}\phi\|_X}{\|\phi\|_X} : \phi \in X \setminus \{0\} \right\}
\]

\[
= \sup \left\{ \frac{\|B\psi\|_X}{\|M\psi\|_X} : \psi \in D_M \setminus \{0\} \right\} .
\]

It is important to notice that, although type I models contain a large family of population models (in particular, those of discrete structure, for which \( \text{dim} \, X < \infty \)), often some structured models cannot be cast into this form.

Indeed, beyond the “standard” case considered above where \( R_0 = \rho(BM^{-1}) \), we can consider another family of population models (which we call type II models as in Barril et al\textsuperscript{6}) where the population distribution at time \( t \geq 0 \) is such that \( u(t) \in X \) and the distribution of newborns per unit time does not belong to \( X \), and so the model cannot be written in the form (1). For instance, in the case of age-structured populations, all newborns are concentrated at age 0, which translates as a boundary condition for an equation of the form \( u'(t) = -M(u(t))u(t) \). More in general, this is very often the case when the individual state space, i.e., the set where the structuring variable lives (its domain) is a continuum, for instance, a real interval, and the set of states at birth is discrete.

In the forthcoming, we will consider models given by conservation laws for densities of individuals living on an interval \( I \), where often the newborns show as a flow crossing the boundary of this domain.

Notice that in the case of type II models, one cannot, in principle, define a next-generation operator.

In order to define \( R_0 \) for type II models, following the approach developed in Barril et al,\textsuperscript{6} we will consider a specially built sequence of type I models in \( X = L^1(I) \):

\[
u'(t) = B_k u(t) - Mu(t) , \ u(0) = u_0 \in X , \ k \in \mathbb{N} . \quad (2)
\]

The linear operator \( M : D_M \subset X \to X \), as before, is such that \( -M \) is the generator of a strongly continuous semigroup of positive linear operators whose spectral bound is strictly negative \( s(-M) < 0 \) and \( B_k : D_{B_k} \subset X \to X \) are positive linear operators, all of finite rank \( m < \infty \) such that \( B_k M^{-1} \) is bounded and \( B_k - M \) is the generator of a strongly continuous semigroup. To fix ideas, let us assume that \( m = 1 \). We further assume that, for any \( k \), \( B_k u = (Lu) \varphi_k \) for some positive linear functional \( L \) and some positive \( \varphi_k \in X \). Notice that \( \varphi_k \) represents the distribution of offspring. Moreover, we assume that the sequence \( M^{-1} \varphi_k \) converges in \( X \) to a certain function \( \psi_{\infty} \in D_L = D_{B_k} \), and that \( LM^{-1} \varphi_k \) converges to \( L\psi_{\infty} \). Notice that the last hypothesis (and the fact that \( \psi_{\infty} \in D_L \)) automatically holds if \( B \) is bounded.
Then we will have that the sequence of basic reproduction numbers corresponding to the approximate models has a limit, which we claim can be named as the basic reproduction number of the limit type II model:

\[
R_0 := \lim_{k \to \infty} R_{0,k} = \lim_{k \to \infty} \rho(B_k M^{-1}) = \lim_{k \to \infty} \rho((LM^{-1}) \varphi_k) = \lim_{k \to \infty} LM^{-1} \varphi_k = L \nu_0 ,
\]

(3)

where \( \rho(\cdot) \) stands for the spectral radius of the positive bounded linear operators involved and where we have used that \( \text{range}(B_k) = \text{span}\{ \varphi_k \} \). Of course, this definition needs a proof of correctness in the sense that it does not depend on the sequence \( \varphi_k \), chosen to approximate the limit model. More precisely, we have to clarify what we do understand by limit model of a sequence of type I models of the form (2) with \( B_k u = (Lu) \varphi_k \) and check that two sequences of functions \( \varphi_k \) and \( \tilde{\varphi}_k \) giving rise to the same limit model are such that \( M^{-1} \varphi_k \) and \( M^{-1} \tilde{\varphi}_k \) tend to the same limit. Thus, let us consider a sequence of conservation laws in the form

\[
\frac{d}{dt} \int_a^b u(s,t)ds = \Phi(a,t) - \Phi(b,t) - \int_a^b \mu(s) u(s,t)dt + Lu(\cdot,t) \int_a^b \varphi_k(s)ds,
\]

(4)

for the rate of change of the population number of individuals whose individual state (size, spatial position, age, etc.) belongs to the (arbitrary) interval \((a, b) \subset I\). Here, \( \Phi(x, t) \) is the flow crossing the point \( x \) at time \( t \), and we assume that it is given by a linear combination of the density \( u \) and its partial derivative \( u_t \). \( \mu \) is the state-dependent per capita death rate (so the integral above gives the rate of loss of individuals with individual state within the interval \([a, b]\)). We also assume that the new individuals are being born according to a fixed distribution of individual states \( \varphi_k \in X \), with \( \int_I \varphi_k(s)ds = 1 \). Hence, the last term stands for the population birth rate. This leads, for a smooth density \( u \), to the following sequence of partial differential equations:

\[
\partial_t u(x, t) = -\partial_x (\gamma(x) u(x, t) - D(x) \partial_x u(x, t)) - \mu(x) u(x, t) + Lu(\cdot, t) \varphi_k(x),
\]

(5)

(where \( D(x) > 0 \) or \( D(x) \equiv 0 \), with nonflux boundary conditions at the (possibly empty) boundary of \( I \). In (5), we can firstly identify an unbounded linear operator, formally written

\[
(Mu)(x) = \partial_x (\gamma(x) u(x) - D(x) \partial_x u(x)) + \mu(x) u(x),
\]

with nonflux boundary conditions, for transition between states and mortality and secondly rank one linear operators \( (B_k u)(x) = (Lu) \varphi_k(x) \) corresponding to reproduction and verify that the model is of the type defined in (2). Let us further assume that the sequence of states distributions at birth \( \varphi_k \) tends to concentrate, for instance, around a point in the closure of \( I \). More precisely, that there exists an individual state \( x_0 \in \bar{I} \) such that for any \([a, b] \subset \bar{I} \), \( \lim_{k \to \infty} \int_a^b \varphi_k(s)ds = 1 \), whenever \( x_0 \in [a, b] \) and \( \lim_{k \to \infty} \int_a^b \varphi_k(s)ds = 0 \) otherwise. Assuming the second case (i.e., \( x_0 \notin [a, b] \)) and making \( k \) go to infinity in (4), we simply obtain the partial differential equation

\[
\partial_t u(x, t) = -\partial_x (\gamma(x) u(x, t) - D(x) \partial_x u(x, t)) - \mu(x) u(x, t),
\]

(6)

for \( x \neq x_0 \).

On the other hand, if \([a, b] \) contains \( x_0 \), making \( k \) go to infinity in (4), we first obtain the integral equation

\[
\frac{d}{dt} \int_a^b u(s, t)ds = \Phi(a, t) - \Phi(b, t) - \int_a^b \mu(s) u(s,t)dt + Lu(\cdot, t),
\]

and afterwards, making that the interval \([a, b] \) collapse to \( x_0 \), we obtain the condition

\[
0 = \lim_{a \to x_0} \Phi(a, t) - \lim_{b \to x_0} \Phi(b, t) + Lu(\cdot, t).
\]

(7)

This can be seen as a boundary condition when \( x_0 \) belongs to the boundary of \( I \). For instance, if \( x_0 \) is the left endpoint of \( I \), we necessarily have \( a = x_0 \) and \( \lim_{a \to x_0} \Phi(a, t) = \Phi(x_0, t) = 0 \) for the nonflux boundary condition, and (7) reduces to a (in general) Robin-type boundary condition.
\[ \lim_{b \to x_0^-} \Phi(b, t) = \gamma(x_0)u(x_0, t) - D(x_0)\partial_x u(x_0, t) = Lu(\cdot, t). \] (8)

Notice, as particular cases, that the latter supplementing the PDE (6) with \( D(x) \equiv 0 \) corresponds to the well-known equation of the linear size-dependent population dynamics when individuals are all born with the same size (and in particular to the equation of the linear age dependent population dynamics if, furthermore, \( \gamma(x) \equiv 1 \)), whereas when \( D(x) \) is strictly positive the PDE (6) could be interpreted as a linear convection–diffusion equation (purely diffusive if \( \gamma(x) \equiv 0 \) for a population living in a one-dimensional habitat such that, in order to reproduce, adult individuals travel instantly to the point \( x_0 \) (a common “nest”) and instantly go back after, to where they were living.

On the other hand, if \( x_0 \) belongs to the interior of \( I \), (7) causes a discontinuity in the flux at the point \( x_0 \). Biologically, this could correspond to a situation like the latter, but where the “nest” is not at the boundary of the domain. From the point of view of the PDE (6), one can consider it on two subdomains of \( I \) separated by \( x_0 \) and with “boundary conditions” at \( x_0 \) given by

\[ \lim_{x \to x_0^-} (\gamma(x)u(x, t) - D(x)\partial_x u(x, t)) - \lim_{x \to x_0^+} (\gamma(x)u(x, t) - D(x)\partial_x u(x, t)) = Lu(\cdot, t). \] (9)

As one could expect, we define the limit model of a sequence of type I models of the form (5) (a particular case of the abstract form 2) as the one given by the partial differential equation (6) plus boundary conditions of the form (8) or (9). Next, we show that different sequences \( \varphi_k \) leading to the same limit model (i.e., concentrating at the same point \( x_0 \)) share the same limit of the sequence \( M^{-1}\varphi_k \) and thus that the basic reproduction number of the limit model (given by Equation 3) is well defined. Indeed, let us denote by \( G(x, s) \) the Green function of the operator \( M \), i.e., such that one can write

\[ (M^{-1}\varphi)(x) = \int_I G(x, s)\varphi(s)ds, \]

(for a comprehensive treatise on Green’s functions, one can see Stakgold and Holst9).

Then, due to the hypotheses on \( \varphi_k \),

\[ \psi_\infty(x) = \lim_{k \to \infty} (M^{-1}\varphi_k)(x) = \lim_{k \to \infty} \int_I G(x, s)\varphi_k(s)ds = G(x, x_0), \]

independently of the choice of the sequence. Moreover we can now write

\[ R_0 := \lim_{k \to \infty} R_{0,k} = \lim_{k \to \infty} LM^{-1}\varphi_k = L\psi_\infty = LG(\cdot, x_0). \] (10)

3 | EXAMPLES

3.1 | A size-dependent model

As a first example, let us consider the type II model associated with the classical (linear) size-dependent population dynamics with potentially unbounded size. Then, (6) reduces to

\[ \partial_t u(x, t) = -\partial_x (\gamma(x)u(x, t)) - \mu(x)u(x, t) =: (Mu)(x, t) \quad x \in (x_0, +\infty), \]

for \( u(\cdot, t) \in L^1(x_0, \infty) \), where \( x_0 \) denotes the individual’s size at birth and with boundary condition

\[ \gamma(x_0)u(x_0, t) = \int_{x_0}^{\infty} \beta(s)u(s, t)ds =: (Lu)(t) \]

(a particular form of (8)). We assume that the individual growth rate \( \gamma(x) \) and the mortality rate \( \mu(x) \) are smooth and bounded below by a positive number and that \( \beta(x) \) is bounded and such that \( \beta(x) \geq 0 \). Moreover, to prevent that the individuals reach infinite size in finite time, we assume \( \int_{x_0}^{\infty} \frac{1}{\gamma(x)}dx = \infty \). We can choose a sequence \( \varphi_k(x) \) concentrating at \( x_0 \) and consider this model as a limit of type I models of the form (5) with \( D(x) \equiv 0 \). Notice that \( -M \) and \( B_k - M \) (where \( B_k u = (Lu)\varphi_k \)) are both generators of strongly continuous semigroups.
Using the variation of constants formula, it is straightforward to compute
\[
(M^{-1}v)(x) = \int_{x_0}^{x} v(s) e^{\int_{x_0}^{x} \frac{\gamma(s)}{\nu(s)} ds} \frac{1}{\gamma(x)} e^{\int_{s}^{x} \frac{\gamma(s)}{\nu(s)} ds} ds,
\]
where \(H\) is the Heaviside function. Hence, \(G(x, s) = \frac{1}{\gamma(x)} e^{\int_{s}^{x} \frac{\gamma(s)}{\nu(s)} ds} H(x - s)\), and we have
\[
\psi_\infty(x) = G(x, x_0) = \frac{1}{\gamma(x)} e^{\int_{x_0}^{x} \frac{\gamma(s)}{\nu(s)} ds}.
\]
Using (10), we obtain
\[
R_0 = L\psi_\infty = \int_{x_0}^{\infty} \frac{\beta(x)}{\gamma(x)} e^{-\int_{x_0}^{x} \frac{\gamma(s)}{\nu(s)} ds} dx,
\]
which coincides with the basic reproduction number in size dependent population dynamics obtained in the literature\(^{4,10}\) as the number of newborns that an individual is expected to produce during his reproductive life.

### 3.2 A size-structured cell population model

Let us start by considering a cell population structured by size \(x\) and such that cells divide when they reach a given size (normalized to 1) giving rise to two daughter cells whose size is not necessarily the same. Indeed, let us assume \(x \in (0, 1)\) and a size distribution of the newborn cells given by a probability density function \(\varphi(x)\). Conservation of the mass during cell division forces that \(\varphi(x) = \varphi(1 - x)\), i.e., the distribution of newborn cells is symmetric with respect to half the mother cell size. In this way, we obtain a type I model given by the PDE
\[
\partial_t u(x, t) = -\partial_x (\gamma(x)u(x, t)) - \mu(x)u(x, t) + 2\gamma(1)u(1, t)\varphi(x), \quad x \in (0, 1),
\]
with zero flux at \(x = 0\) for the density of cells \(u(x, t)\) and where \(\gamma\) is the individual growth rate, \(\mu\) the mortality rate, and the last term is the (distributted) birth rate. We assume the same hypotheses on \(\gamma\) and \(\mu\) of the previous section. The PDE is of the form (5) with \(D(x) \equiv 0\) as before.

Notice that in this case the birth operator \((Bu)(x) = (Lu)\varphi(x) = 2\gamma(1)u(1)\varphi(x)\), despite being of rank 1, is only relatively bounded with respect to the linear operator \((-Mu)(x) = -\partial_x (\gamma(x)u(x)) - \mu(x)u(x)\) with nonflux boundary condition at the left hand end \(x_0 = 0\) (i.e., \(B\) is not bounded as a linear operator in \(L^1\) but \(BM^{-1}\) is bounded, which amounts to that \(LM^{-1}\) is a bounded linear form).

In order to be in the hypotheses of Section 2, we need \(B - M\) to be the infinitesimal generator of a strongly continuous positive semigroup. The fact that \(B\) is relatively bounded is in general not enough to ensure that \(B - M\) is a generator of a strongly continuous semigroup.\(^{11}\) Nevertheless, it suffices that \(B\) is a bounded linear operator in the domain of \((-M)\) endowed with the graph norm (see Engel and Nagel\(^{11}\) Cor. III.1.5). For (12), this is satisfied provided that \(\varphi \in D(-M) = \{u \in W^{1,1}(0, 1) : u(0) = 0\}\). Indeed, we have for \(u \in D_M\), and using that 0 belongs to the resolvent set of the operator \(M\),
\[
\|Bu\|_{D_M} = \|MBu\| = \|M(Lu)\varphi\| = \|Lu\|\|M\varphi\| = \|LM^{-1}Mu\| \|M\varphi\| \leq \|M\varphi\|\|L^{-1}M\|\|Mu\| = C\|u\|_{D_M},
\]
where the norms without subscript are \(L^1\)-norms.

Since the mortality/transition operator \(M\) is exactly the same as in the previous section, the Green function is
\[
G(x, s) = \frac{e^{-\int_{s}^{x} \frac{\gamma(s)}{nu(s)} ds}}{\gamma(x)} H(x - s).
\]
So the basic reproduction number for this model is given by
\[
R_0 = LM^{-1}\varphi = 2\gamma(1)(M^{-1}\varphi)(1) = 2\gamma(1) \int_{0}^{1} G(1, s)\varphi(s)ds = 2 \int_{0}^{1} e^{-\int_{s}^{1} \frac{\gamma(s)}{nu(s)} ds} \varphi(s)ds.
\]
A bit less realistic but apparently simpler, one can alternatively assume that the division is perfectly symmetric. To deal with this assumption, similarly to what we have done in the previous example, we can choose a sequence of functions \( \varphi_k \in D(-M) \) concentrating at \( x_0 = 1/2 \) (for instance, \( \varphi_k(x) = a_k(x(1-x)e^{-k|x-x|^{2/1}} \) with \( a_k \) such that \( \int_0^1 \varphi_k = 1 \) and consider the model with symmetric division as a limit of a sequence of type I models as the ones described above (of the form (5)).

As limiting equation, we get
\[
\partial_t u(x,t) = -\partial_x (\gamma(x) u(x,t)) - \mu(x) u(x,t),
\]
with “boundary condition” (according to (9))
\[
\gamma \left( \frac{1}{2} \right) \lim_{x \to \left( \frac{1}{2} \right)^+} u(x,t) - \lim_{x \to \left( \frac{1}{2} \right)^-} u(x,t) \right) = Lu(.,t) = 2\gamma(1) u(1,t),
\]
which can be considered a birth term giving the influx of new cells (double of the number of cells that disappear because they divide).

We have that
\[
M^{-1} \varphi_k = \int_0^1 G(\cdot, s) \varphi_k(s) ds
\]
tends to \( G \left( \cdot, \frac{1}{2} \right) \) in \( L^1(0,1) \) and uniformly on \( (0,1) \setminus \left( \frac{1}{2} - \varepsilon, \frac{1}{2} + \varepsilon \right) \) (for any \( \varepsilon < \frac{1}{2} \)).

Therefore, the basic reproduction number for the limit model can be computed as
\[
R_0 = \lim R_{0,k} = \lim LM^{-1} \varphi_k = \lim 2\gamma(1) \int_0^1 G(1,s) \varphi_k(s) ds = 2\gamma(1) G \left( 1, \frac{1}{2} \right) = 2e^{-\int_0^{\frac{1}{2}} \frac{\mu(s)}{\gamma(s)} ds}.
\]

Finally notice that, for any initial condition, the solution of the initial value problem for (13) and (14) will vanish identically on the interval \( \left( 0, \frac{1}{2} \right) \) after a finite time, which means that we can consider equivalently the PDE (13) on the interval \( \left( \frac{1}{2}, 1 \right) \) with boundary condition \( \gamma \left( \frac{1}{2} \right) u \left( \frac{1}{2}, t \right) = 2\gamma(1) u(1,t) \).

### 3.3.1 Size-structured particular model with diffusion

Let us consider a closed population living in a specific habitat where individuals are classified according to some biometric measure (physiological size), which we assume to evolve in a diffusive way, i.e., random fluctuation in the individual growth. For some examples on structured population models in structure space, see, for instance, Hadeler,12 Pugliese and Milner,13 and Farkas and Hinow.14

Let \( X = L^1(x_0, \infty), x_0 \geq 0 \), and let \( u(\cdot, t) \in X \) be the density with respect to size at time \( t \geq 0 \). The nonlinear problem is described as follows:

\[
\begin{align*}
\frac{\partial u(x,t)}{\partial t} + \frac{\partial_x}{\partial x} \left[ \gamma(x, S(t)) u(x,t) - D \frac{\partial_x}{\partial x} u(x,t) \right] + \mu(x, S(t)) u(x,t) &= 0 \\
\gamma(x_0, S(t)) u(x_0, t) - D \frac{\partial_x}{\partial x} u(x_0, t) &= \int_{x_0}^{\infty} \beta(x, S(t)) u(x,t) \, dx \\
\frac{S(t)}{x_0} &= \int_{x_0}^{\infty} \sigma(x) u(x,t) \, dx,
\end{align*}
\]

where \( S(t) \) is a weighted population size with \( \sigma(x) \geq 0 \), \( \gamma(x, S(t)) > 0 \) is the individual growth rate, i.e., \( \frac{dx}{dt} = \gamma(x, S(t)) \), \( x(0) = x_0, D > 0 \) is the diffusion coefficient, \( \beta(x, S(t)) \geq 0 \) is the fertility rate, and \( \mu(x, S(t)) \geq 0 \) is the mortality rate. Notice that all newborns are assumed to have size \( x_0 \geq 0 \), and growth and vital processes here are density-dependent accounting for limited resources (crowding effects) and size-specific (heterogeneity of the population). Finally, notice that we would get the classical size-structured model if we had \( D \equiv 0 \).

The linearization around the trivial steady-state is given by

\[
\begin{align*}
\frac{\partial u(x,t)}{\partial t} + \frac{\partial_x}{\partial x} \left[ \gamma(x) u(x,t) - D \frac{\partial_x}{\partial x} u(x,t) \right] + \mu(x) u(x,t) &= 0 \\
\gamma(x_0) u(x_0, t) - D \frac{\partial_x}{\partial x} u(x_0, t) &= \int_{x_0}^{\infty} \beta(x) u(x,t) \, dx,
\end{align*}
\]
where we set \( \gamma(x) := \gamma(x, 0) \), \( \beta(x) := \beta(x, 0) \), and \( \mu(x) := \mu(x, 0) \) with an abuse of notation. We assume the same hypotheses on \( \gamma(x) \), \( \mu(x) \), and \( \beta(x) \) as in Section 3.1.

**Remark 1.** Assuming the nonlinearity constant \( S \) in (15), and having then \( \gamma(x, S) \), \( \beta(x, S) \) and \( \mu(x, S) \) as functions of \( x \) uniquely, one could define the so-called net reproduction function for the nonlinear model \( R(S) \). This is useful if one is interested in finding nontrivial equilibria of (15) since the total weighted population at equilibrium is given by the solution of \( R(S) = 1 \).

We can choose \( \varphi_k(x) = k \mathbb{1}_{[x_0, x_0 + 1/k]}(x) \) and consider model (16) as a limit of the following sequence of type I models in \( X = L^1(x_0, \infty) \):

\[
\begin{aligned}
\int \frac{d\tau(x, t) + d\varsigma [\gamma(x)u(x, t) - D\partial_t u(x, t)] + \mu(x)u(x, t)}{\gamma(x_0)u(x_0, t) - D\partial_t u(x_0, t) = 0},
\end{aligned}
\]

Here, the birth operators are rank one bounded linear operators of the form \( B_k : X \to X \),

\[
(B_k \phi)(x) = \int_{x_0}^{\infty} \beta(x) \phi(x) dx \cdot k \mathbb{1}_{[x_0, x_0 + 1/k]}(x),
\]

and the transition/mortality operator is given by the unbounded linear operator \( M : D_M \subset X \to X \),

\[
(M \phi)(x) = (\gamma(x) \phi(x) - D\phi'(x))' + \mu(x) \phi(x),
\]

with domain \( D_M = \{ \phi \in X : \gamma \phi - D \phi' \in X, \text{ and } \gamma(x_0) \phi(x_0) - D \phi'(x_0) = 0 \} \).

The fact that \(-M\) is the generator of a positive semigroup goes back to the work by Feller, Hille, and Yosida (see Feller and the references therein). Since \( B_k \) is bounded, \( B_k - M \) is the infinitesimal generator of a positive semigroup.

For each \( k \geq 1 \), \( R_{0,k} \) is computed as the largest \( \lambda \geq 0 \) for which the operator \( B_k - \lambda M \) does not have a bounded inverse; that is, we have to study the problem \( B_k \psi - \lambda M \psi = \xi \), for \( \psi \in D, \xi \in X \), which is

\[
\int_{x_0}^{\infty} \beta(x) \psi(x) dx \cdot k \mathbb{1}_{[x_0, x_0 + 1/k]}(x)(x - \lambda \left[ (\gamma(x) \psi(x) - D\psi'(x))' + \mu(x) \psi(x) \right]) = \xi(x),
\]

and integrating the first equation along the whole size-span, we get

\[
\int_{x_0}^{\infty} (\beta(x) - \lambda \mu(x)) \psi(x) dx = \int_{x_0}^{\infty} \xi(x) dx.
\]

There is a special case in which the basic reproduction number has an explicit expression, namely, the “proportional vital rates case”:

\[
\beta(x) = \bar{\beta} \cdot \mu(x), \quad \bar{\beta} \geq 0,
\]

where the relation above becomes \( \int_{x_0}^{\infty} \mu(x) \psi(x) dx = \int_{x_0}^{\infty} \xi(x) dx \), and therefore the relation cannot be inverted if \( \lambda = \bar{\beta} = R_{0,k} \). Finally, we get \( R_0 = \lim_{k \to \infty} R_{0,k} = \bar{\beta} \), which in this case is independent of the size-dependent growth and diffusion processes.

Notice that (11) gives the same \( R_0 \) under hypothesis (17):

\[
R_0 = \int_{x_0}^{\infty} \frac{\beta(x)}{\gamma(x)} e^{-\int_{x_0}^{x} \frac{\beta(y)}{\gamma(y)} dy} dx = \bar{\beta}.
\]
### 3.4 Age-structured model with diffusion in age

In this section, we consider a linear age-structured population model for the dynamics of a closed population of individuals (animals, cells, ... ) structured by physiological age \( a \geq 0 \) with diffusion \( D \geq 0 \):

\[
\begin{align*}
\partial_t u(a,t) + \partial_a u(a,t) + \mu u(a,t) &= D \partial_{aa} u(a,t), \\
 u(0,t) - D \partial_a u(0,t) &= \int_0^\infty \beta(a) u(a,t) \, da.
\end{align*}
\] (18)

We interpret physiological age as an internal variable associated with the physiological development of an individual, normally distributed and with expected value equal to the chronological age. The physiological (or biological) age of an individual, as opposed to chronological age or time since birth, varies in a diffusive way. For papers on diffusion age-structured problems, see Brewer\textsuperscript{17} and Kakumani and Tumuluri.\textsuperscript{18} Notice that (18) is a particular case of (16).

The main goal is to compute the basic reproduction number \( R_0^D \) using (3) for model (18) and to compare it with the classical age-structured population model corresponding to \( D = 0 \).

Looking for exponential solutions of system (18), one obtains a characteristic equation from which the following can be computed as the solution \( v \in L^1(0, \infty) \) of the boundary value problem

\[
\begin{align*}
\nu'(a) + \mu \nu(a) - D\nu''(a) &= \phi(a), \\
\nu(0) &= D\nu'(0),
\end{align*}
\] (20)

for a given datum \( \phi \in L^1(0, \infty) \). Let us call

\[
\lambda_1 = \frac{1}{2D} \left( 1 + \sqrt{1 + 4D\mu} \right) > 0, \quad \lambda_2 = \frac{1}{2D} \left( 1 - \sqrt{1 + 4D\mu} \right) < 0.
\]

The general solution of the second-order inhomogeneous linear ODE above can be written as follows:

\[
\nu(a) = \frac{1}{\sqrt{1 + 4D\mu}} \left( e^{\lambda_1 a}(c_1 + \int_0^a e^{-\lambda_1 s}\phi(s)ds) + e^{\lambda_2 a}(c_2 - \int_0^a e^{-\lambda_2 s}\phi(s)ds) \right).
\]

By imposing that \( \nu \) is integrable, we get \( c_1 = 0 \), and using the boundary condition at \( a = 0 \) straightforwardly, we obtain \( c_2 = -\frac{\lambda_2}{\lambda_1} \int_0^\infty e^{-\lambda_2 s}\phi(s)ds \), and thus the solution of (20) can be written as follows:

\[
\nu(a) = \frac{1}{\sqrt{1 + 4D\mu}} \left( \int_a^\infty e^{\lambda_1 (s-a)}\phi(s)ds + \int_0^a e^{\lambda_2 (a-s)}\phi(s)ds - \frac{\lambda_2}{\lambda_1} \int_0^\infty e^{\lambda_2 a-\lambda_2 s}\phi(s)ds \right).
\]

Therefore, we can write

\[
(M^{-1}\phi)(a) = \int_0^\infty G(a,s)\phi(s)ds,
\] (21)

where

\[
G(a,s) = \frac{1}{\sqrt{1 + 4D\mu}} \left( e^{\lambda_1 (a-s)}H(s-a) + e^{\lambda_2 (a-s)}H(a-s) - \frac{\lambda_2}{\lambda_1} e^{\lambda_2 a-\lambda_2 s} \right).
\]
Along the lines of Barril et al. and Section 2, we introduce a sequence of "type I" models, which approximate (18):

\[
\begin{aligned}
\partial_t u(a, t) + \partial_a u(a, t) + \mu u(a, t) &= D \partial_{aa} u(a, t) + \int_0^\infty \beta(a) u(a, t) \, da \, k1_{[1/k, k]}(a) \\
0 &= D \partial_a u(0, t) = 0.
\end{aligned}
\]  

(22)

Notice that (22) has a biological meaning on its own. That is, it corresponds to assuming that the newborns size (or physiological age) is distributed uniformly on a small interval around the minimal size 0. Similarly to Section 3.2, this is an assumption at least as reasonable as assuming that the size of the newborns is concentrated at a given value, for instance, 0.

Here, the birth operator \( B_k u := \int_0^\infty \beta(a) u(a, t) \, da \, k1_{[1/k, k]} \) has a one-dimensional range spanned by the characteristic function of the interval \([0, 1/k]\). So \( Lv := \int_0^\infty \beta(a) v(a) \, da \) is a bounded linear form given by the \( L^\infty \) function \( \beta \). Consequently, the basic reproduction number for (22) can be computed as

\[
R_{0,k} = \rho (B_k M^{-1}) = LM^{-1}(k1_{[0,1/k]})(a) = \int_0^\infty \beta(a) M^{-1}(k1_{[0,1/k]})(a) \, da.
\]

In this case, a straightforward computation using (21) gives

\[
(M^{-1}(k1_{[0,1/k]}))(a) = \frac{1}{1 + 4\mu D} \left( \int (1 - ak) \left( F \left( \frac{\lambda_1}{k} \right) - F \left( \frac{\lambda_2}{k} \right) \right) \right) 1_{[0,1/k]}(a) + \left( F \left( \frac{\lambda_2}{k} \right) - \frac{\lambda_2}{\lambda_1} F \left( \frac{\lambda_1}{k} \right) \right) e^{\lambda_2 a},
\]

(23)

where \( F(x) := \frac{1-e^x}{x} \) for \( x \neq 0, F(0) = 1 \).

We now proceed to compute the basic reproduction number for the limit model (18). So let us compute the \( L^1 \)-limit of the sequence \( M^{-1}(k1_{[0,1/k]}) \). First, notice that \( F(x) \) is an analytic function and that its first derivative is negative and its second derivative is positive. Since \( F \) is decreasing and \( \lambda_2 < \lambda_1 \), the coefficient of \( 1_{[0,1/k]} \) in (23) is nonpositive, implying

\[
(M^{-1}(k1_{[0,1/k]}))(a) \leq \frac{1}{1 + 4\mu D} \left( F \left( \frac{\lambda_2}{k} \right) - \frac{\lambda_2}{\lambda_1} F \left( \frac{\lambda_1}{k} \right) \right) e^{\lambda_2 a}.
\]

On the other hand, let us consider the function \( G(x) = F \left( \frac{\lambda_2}{\lambda_1} x \right) - \frac{\lambda_2}{\lambda_1} F(x) \), whose derivative \( G'(x) = \frac{\lambda_2}{\lambda_1} \left( F' \left( \frac{\lambda_2}{\lambda_1} x \right) - F'(x) \right) \) is positive for \( x > 0 \) since \( \frac{\lambda_2}{\lambda_1} < 0 \) and \( F'(x) > 0 \). Therefore, \( F \left( \frac{\lambda_2}{k} \right) - \frac{\lambda_2}{\lambda_1} F \left( \frac{\lambda_1}{k} \right) = G \left( \frac{\lambda_1}{k} \right) \) decreases with \( k \). So we obtain the following bound, independent of \( k \),

\[
(M^{-1}(k1_{[0,1/k]}))(a) \leq \frac{1}{1 + 4\mu D} \left( F(\lambda_2) - \frac{\lambda_2}{\lambda_1} F(\lambda_1) \right) e^{\lambda_2 a}.
\]

\[ (M^{-1}(k1_{[0,1/k]}))(a) \] converges pointwise to \( \psi_\infty(a) := \frac{(1-\frac{\lambda_2}{\lambda_1}) e^{\lambda_2 a}}{\sqrt{1+4\mu D}} \) and hence the convergence is also in \( L^1 \) by the Lebesgue dominated convergence theorem. Notice that the limit function does not belong to the domain of the operator \(-M\) because it does not satisfy the boundary condition. Also notice that \( \psi_\infty(a) = G(a, 0) \). Along the lines of Section 2, we compute the basic reproduction number of system (18) as

\[
R_0^D = \lim R_{0,k} = L \psi_\infty = LG(\cdot, 0) = \int_0^\infty \beta(a) \frac{(1-\frac{\lambda_2}{\lambda_1}) e^{\lambda_2 a}}{\sqrt{1+4\mu D}} \, da = \frac{2}{1+\sqrt{1+4\mu D}} \int_0^\infty \beta(a) e^{(1-\sqrt{1+4\mu D})a} \, da,
\]

which is the basic reproduction number for the diffusion age-structured population model (18) and coincides with the conjecture given at the beginning of the subsection. For an alternative computation of \( R_0^D \) using the solution semigroup, we refer the reader to the Appendix. For a constant fertility rate, i.e., \( \beta(a) \equiv \bar{\beta} \), the basic reproduction number is given by

\[
R_0^D = \frac{\bar{\beta}}{\mu}, \quad \text{for all } D \geq 0,
\]
CONCLUSIONS

so it is independent of the diffusion process.

For age-specific fertilities, an interesting issue is the dependence of $R_0^D$ on the diffusion coefficient $D$. As expected, $R_0^D$ does not depend on $D$ if the fertility function is a constant. On the other hand, we already know that it tends to the basic reproduction number without diffusion when $D$ tends to 0. It is also very easy to show that it tends to 0 for $D$ tending to $\infty$ whenever the fertility function $\beta$ is integrable, albeit it does it slowly ($\frac{1}{\sqrt{D}}$). More precisely,

$$
\lim_{D \to \infty} \sqrt{D} R_0^D = \lim_{D \to \infty} \frac{2\sqrt{D}}{1 + \sqrt{1 + 4D\mu}} \int_0^\infty \beta(a)e^{-\frac{2a}{\sqrt{1+4D\mu}}}da = \frac{1}{\sqrt{\mu}} \int_0^\infty \beta(a)da,
$$

as can be seen using the Lebesgue dominated convergence theorem. As for the biological interpretation, an integrable fertility function combined with a large value of the parameter $D$ entails too many unfertile individuals.

However, this does not mean that $R_0^D$ is always a monotone (decreasing) function of $D$. For instance, the particular case $\beta(a) = \beta_0 a^2 e^{-a}$ (see Webb\textsuperscript{20} for a discussion on the choice of this birth function) leads to $R_0^D = \frac{32\beta_0 D^3}{(2D+\sqrt{1+4D\mu}+1)^4}$, which tends to $\frac{2\beta_0}{(\mu+1)^4}$ when $D$ goes to 0 (the value of $R_0$ for $D = 0$) but, for $\mu > 1/2$, it has a maximum value $\frac{8\beta_0}{27\mu}$ (greater than $\frac{2\beta_0}{(\mu+1)^4}$) at $D = 4\mu - 2$ (see Figure 1). Biologically, this could be explained because for small values of $D$, individuals die before reaching an age with high fertility, whereas for large values of $D$, individuals grow old too fast are then fertile for a short period of their life.

On the other hand, a very small fertility function in early ages like the one above leads to think in the case of a maturation age below which the individuals do not reproduce. For instance, if $\beta(a)$ vanishes for $a < 1$, and it is a constant $\beta_0$ for $a > 1$, and then $R_0^D = \frac{\beta_0 e^{-a}}{\mu} \int_0^a G(\cdot,s)ds$ is an increasing function of $D$ ranging from $\frac{\beta_0 e^{-1}}{\mu}$ at $D = 0$ to $\frac{\beta_0}{\mu}$ (the basic reproduction number without maturation delay) at infinity. Then, the presence of a moderate diffusion in age tends to increase $R_0$ and hence the survival chances of a population.

4 CONCLUSIONS

In this paper, we have considered continuously structured population models given by conservation laws, and we have shown useful formulas for the basic reproduction number $R_0$ based on the linear functional $L$ (birth event), the Green function $G(x,s)$ (the integral kernel of $M^{-1}$, the inverse of the linear operator $M$ giving transitions, i.e., events other than births) and the offspring distributions $\varphi$ and $\varphi_k$. Namely, for type I models:

$$
R_0 = \rho(BM^{-1}) = (LM^{-1}\varphi) = L \int_I G(\cdot,s)\varphi(s)ds.
$$

For type I models approximating type II models:

$$
R_{0,k} = \rho(B_kM^{-1}) = (LM^{-1}\varphi_k) = L \int_I G(\cdot,s)\varphi_k(s)ds, \quad k \in \mathbb{N}.
$$

And finally, for type II models as limit of type I models:

$$
R_0 := \lim_{k \to \infty} R_{0,k} = \lim_{k \to \infty} L \int_I G(\cdot,s)\varphi_k(s)ds = LG(\cdot,x_0),
$$

FIGURE 1 A graph of $R_0^D$ showing values larger than 1 for moderate diffusion coefficient [Colour figure can be viewed at wileyonlinelibrary.com]
where states at birth are concentrated at \( x_0 \in \tilde{I} \).

Notice that we do not need to choose specific \( \varphi_k \) necessarily since we can apply the last formula above for type II models. This limit approach, in contrast to heuristic approaches, allows us to formally show that what we have computed is actually the basic reproduction number of the model. Nevertheless, if one is interested in type I models (because they are biologically relevant by themselves) or, in a more general setting where we have just a definition:

\[
R_0 := \lim_{k \to \infty} R_{0,k} = \lim_{k \to \infty} \rho(B_k M^{-1}),
\]

the choice of the ingredients (i.e., how to define operators \( B_k \) approximating \( B \)) would be important for several reasons:

- Some \( \varphi_k \) would describe more accurately the birth distribution.
- The rate of convergence of the sequence would be an indication of the goodness of the chosen sequence.
- Simplicity in the computation of \( R_{0,k} \).
- The constrains of the model as in the example of symmetric division in Section 3.2 where we need \( \varphi_k \) to be in the domain of the transition/mortality operator.

APPENDIX A: AN ALTERNATIVE COMPUTATION OF THE BASIC REPRODUCTION NUMBER FOR THE AGE-STRUCTURED MODEL WITH DIFFUSION USING THE SOLUTION SEMIGROUP

An explicit expression for the solution semigroup of the system

\[
\begin{align*}
\partial_t v(a, t) + \partial_a v(a, t) + \mu v(a, t) &= D \partial_{aa} v(a, t), \\
v(0, t) - D \partial_a v(0, t) &= 0, \\
v(a, 0) &= v_0(a),
\end{align*}
\]

which is the initial value problem for model (18) with zero fertility rate, is possible by means of the Green function.

First notice that this initial boundary value problem can be rewritten as an initial boundary problem for the heat equation satisfying a slightly different Robin-type boundary condition by means of the change of dependent variable

\[ v(a, t) = e^{\frac{\mu}{D} \cdot t} u(a, t). \]

Indeed, a straightforward computation shows that \( v \) is a solution of (A1) if and only if \( u \) solves

\[
\begin{align*}
\partial_t u(a, t) &= D \partial_{aa} u(a, t), \\
\partial_a u(0, t) &= 0, \\
u(a, 0) &= e^{-\frac{\mu}{D} s} v_0(a).
\end{align*}
\]

A Green function for Problem (A2) can be found in the book of Cole et al.\(^{21}\) cataloged as X30:

\[ G_{X30}(a, s, t) = \frac{e^{-\frac{a^2 s^2}{4D t}} + e^{-\frac{(a+s)^2}{4D t}}}{2\sqrt{\pi D t}} - \frac{e^{\frac{a^2 s^2}{2D t}}}{2D} \left( 1 - \text{erf} \left( \frac{a + s + t}{2\sqrt{D t}} \right) \right). \]

So the solution of (A2) is given by

\[ u(a, t) = \int_0^\infty G_{X30}(a, s, t)e^{-\frac{s}{D} v_0(s)}ds, \]

and consequently, that of (A1) by

\[ (T(t)v_0)(a) := v(a, t) = \int_0^\infty G_0(a, s, t)v_0(s)ds, \]

where

\[
G_0(a, s, t) = e^{\frac{\mu}{D} \cdot s} \cdot \left( e^{-\frac{a^2 s^2}{4D t}} + e^{-\frac{(a+s)^2}{4D t}} - e^{\frac{a^2 s^2}{2D t}} \left( 1 - \text{erf} \left( \frac{a + s + t}{2\sqrt{D t}} \right) \right) \right).
\]

With the aim of writing the next-generation operator, after interchanging the integration order, we can write

\[
\int_0^\infty (T(t)v)(a)dt = \int_0^\infty \int_0^\infty G_0(a, s, t) dt v(s) ds.
\]
Now, proceeding in a similar manner as we did in Section 3.4, we consider system (22), and setting \( v_k = k_{1[0,1/k]} \), we can write
\[
\int_0^\infty (T(t)v_k)(a) \, dt = k \int_0^{1/k} \int_0^\infty G_0(a, s, t) \, dt \, ds \to \int_0^\infty G_0(a, 0, t) \, dt,
\]
where
\[
G_0(a, 0, t) = e^{-\mu t} \left( e^{-\frac{a^2}{4Dt}} - \frac{e^{\frac{a}{2D}}}{2D} \left( 1 - \text{erf} \left( \frac{a + t}{2\sqrt{Dt}} \right) \right) \right).
\]
Arguing as above,
\[
R_0^D = \lim_{k \to 0} R_{0,k} = \lim_{k \to 0} \int_0^\infty \beta(a) (T(t)v_k)(a) \, dt = \int_0^\infty \beta(a) \int_0^\infty G_0(a, 0, t) \, dt \, da,
\]
and the only thing left is the computation of the integral of \( G_0(a, 0, t) \) with respect to \( t \) on \((0, \infty)\).
Indeed, a standard argument based on “completing squares” gives
\[
\int_0^\infty e^{-\mu t} \cdot \frac{e^{-\frac{a^2}{4D}}}{{\sqrt{\pi D}t}} \, dt = 2e^{\frac{a^2}{4D}} \frac{(1 - \sqrt{1 + 4D\mu})}{\sqrt{1 + 4D\mu}}, \tag{A3}
\]
whereas for the second term, we have
\[
\int_0^\infty e^{-\mu t} \frac{e^{\frac{a}{2D}}}{2D} \left( 1 - \text{erf} \left( \frac{a + \tau}{2\sqrt{Dt}} \right) \right) \, d\tau = \frac{e^\frac{a}{2D}}{2D} \int_0^\infty e^{-\mu t} \int_{\frac{a^2}{2\sqrt{Dt}}}^\infty \frac{2}{\sqrt{\pi}} e^{-x^2} \, dx \, d\tau,
\]
which, after changing integration order, equals
\[
\frac{e^\frac{a}{2D}}{\mu D\sqrt{\pi}} \int_0^\infty e^{-x^2} \int_{\frac{a^2}{2\sqrt{Dt}}}^\infty e^{-\mu t} \, dx \, d\tau \int_0^\infty \sqrt{\frac{\pi}{a}} e^{1+\mu D} e^{-\frac{a^2}{4D} + \frac{a^2}{2D}} \sqrt{\frac{\pi}{a}} e^{-\mu t} \, dx \, ds,
\]
where we replaced \( x = \frac{1}{2} \left( s + \frac{a}{\sqrt{2D}} \right), \, s > \sqrt{\frac{a}{2D}} \) in the first integral and \( x = \frac{1}{2} \left( s + \frac{a}{\sqrt{2D}} \right), \, s \in \left( 0, \sqrt{\frac{a}{2D}} \right) \) in the second one. This finally gives
\[
\frac{e^{1+\mu D} e^\frac{a}{2D}}{2\mu D\sqrt{\pi}} \left( \int_0^\infty e^{-\frac{a^2}{4D} + \frac{a^2}{2D}} \sqrt{\frac{\pi}{a}} e^{-\mu t} \, dx \, ds \right) - \int_0^\infty \frac{\sqrt{\pi}}{2D} e^{\frac{a^2}{4D} + \frac{a^2}{2D}} \sqrt{\frac{\pi}{a}} e^{-\mu t} \, dx \, ds
\]
\[
= \frac{e^{\frac{a^2}{4D}}}{4\mu D} \left[ e^{\frac{a}{2D}} \text{erf} \left( \frac{s}{2} + \frac{a}{\sqrt{2D}} \right) - e^{\frac{a}{2D}} \text{erf} \left( \frac{s}{2} - \frac{a}{\sqrt{2D}} \right) \right]_0^\infty
\]
\[
+ \frac{1}{\sqrt{1 + 4D\mu}} \left[ e^{\frac{a}{2D}} \text{erf} \left( \frac{s}{2} + \frac{a}{\sqrt{2D}} \right) - e^{\frac{a}{2D}} \text{erf} \left( \frac{s}{2} - \frac{a}{\sqrt{2D}} \right) \right]_0^\infty
\]
\[
= \frac{e^{\frac{a^2}{4D}}}{2\mu D} \left( 1 - \frac{1}{\sqrt{1 + 4\mu D}} \right),
\]
which can be checked by direct differentiation. Subtracting the last expression from (A3), one easily obtains (19).
