How to count in hierarchical landscapes:
a ‘full’ solution to mean-field complexity

Jaron Kent-Dobias and Jorge Kurchan

Laboratoire de Physique de l’Ecole Normale Supérieure, Paris, France

September 5, 2022

Abstract

We derive the general solution for counting the stationary points of mean-field complex landscapes. It incorporates Parisi’s solution for the ground state, as it should. Using this solution, we count the stationary points of two models: one with multi-step replica symmetry breaking, and one with full replica symmetry breaking.

1 Introduction

The computation of the number of metastable states of mean field spin glasses goes back to the beginning of the field. Over forty years ago, Bray and Moore [1] attempted the first calculation for the Sherrington–Kirkpatrick model, in a paper remarkable for being one of the first applications of a replica symmetry breaking (RSB) scheme. As was clear when the actual ground-state of the model was computed by Parisi with a different scheme, the Bray–Moore result was not exact, and the problem has been open ever since [2]. To date, the program of computing the number of stationary points—minima, saddle points, and maxima—of mean-field complex landscapes has been only carried out for a small subset of models, including most notably the (pure) $p$-spin model ($p > 2$) [3–6] and for similar energy functions inspired by molecular biology, evolution, and machine learning [7–9]. In a parallel development, it has evolved into an active field of probability theory [10–12].

In this paper we present what we argue is the general replica ansatz for the number of stationary points of generic mean-field models, which we expect to include the Sherrington–Kirkpatrick model. It reproduces the Parisi result in the limit of small temperature for the lowest states, as it should.

To understand the importance of this computation, consider the following situation. When one solves the problem of spheres in large dimensions, one finds that there is a transition at a given temperature to a one-step replica symmetry breaking (1RSB) phase at a Kauzmann temperature, and, at a lower temperature, another transition to a full RSB (FRSB) phase (see [13, 14], the so-called ‘Gardner’ phase [15]). Now, this transition involves the lowest equilibrium states. Because they are obviously unreachable at any reasonable timescale, a common question is: what is the signature of the Gardner transition line for higher than equilibrium energy-densities? This is a question whose answers are significant to interpreting the results of myriad experiments and simulations [16–25] (see, for a review [26]). For example, when studying ‘jamming’ at zero temperature, the question is posed as ‘on what side of the 1RSB–FRSB transition are high energy (or low density) states reachable dynamically?’ One approach to answering such questions makes use of ‘state following,’ which tracks metastable thermodynamic configurations to their zero temperature limit [27–31]. In the present paper we give a purely geometric approach: we consider the local energy minima at a given energy and study their number and other properties: the solution involves a replica-symmetry breaking scheme that is well-defined, and corresponds directly to the topological characteristics of those minima.

Perhaps the most interesting application of this computation is in the context of optimization problems, see for example [32–34]. A question that appears there is how to define a ‘threshold’ level, the lowest energy level that good algorithms can expect to reach. This notion was introduced in the context of the pure $p$-spin models, as the energy at which level sets of the energy in phase-space percolate, explaining why dynamics never go below that level [35]. The notion of a ‘threshold’ for more complicated landscapes has later been invoked several times, never to our knowledge in a clear and unambiguous way. One of the purposes of this paper is to give a sufficiently detailed characterization of a general landscape so that a meaningful general notion of threshold may be introduced – if this is at all possible.

The format of this paper is as follows. In §2, we introduce the mean-field model of study, the mixed $p$-spin spherical model. In §3 we review details of the equilibrium solution that are relevant to our study of the landscape complexity. In §4 we derive a generic form for the complexity. In §5 we make and review the hierarchical replica symmetry breaking ansatz used to solve the complexity. In §6 we write down the solution in a specific and limited regime, which is nonetheless helpful as it gives a foothold for numerically computing the complexity everywhere else. §7 explains aspects of the solution specific to the case of full RSB, and derives the replica symmetric to full FRSB (RS–FRSB) transition line. §8 details the landscape topology of two example models: a $3 + 16$ model with a 2RSB ground state and a 1RSB complexity, and a $2 + 4$ with a FRSB ground state and a FRSB complexity. Finally §9 provides some interpretation of our results.

2 The model

For definiteness, we consider the mixed $p$-spin spherical model, whose Hamiltonian

$$H(s) = -\sum_p \frac{1}{p!} \sum_{i_1 \ldots i_p} J^{(p)}_{i_1 \ldots i_p} s_{i_1} \cdots s_{i_p}$$

is defined for vectors $s \in \mathbb{R}^N$ confined to the sphere $\|s\|^2 = N$. The coupling coefficients $J$ are taken at random, with zero mean and variance $(\langle J^{(p)} \rangle)^2 = a_p p! / 2N^{p-1}$ chosen so that the energy is typically extensive. The overbar
will always denote an average over the coefficients \( J \). The factors \( a_p \) in the variances are freely chosen constants that define the particular model. For instance, the so-called ‘pure’ models have \( a_p = 1 \) for some \( p \) and all others zero.

The variance of the couplings implies that the covariance of the energy with itself depends on only the dot product (or overlap) between two configurations. In particular, one finds

\[
H(s_1)H(s_2) = NF\left(\frac{s_1 \cdot s_2}{N}\right)
\]

(2)

where \( f \) is defined by the series

\[
f(q) = \frac{1}{2} \sum_p a_p q^p
\]

(3)

One needn’t start with a Hamiltonian like (1), defined as a series: instead, the covariance rule (2) can be specified for arbitrary, non-polynomial \( f \), as in the ‘toy model’ of Mézard and Parisi [36].

The family of mixed \( p \)-spin models may be considered as the most general models of generic Gaussian functions on the sphere. To constrain the model to the sphere, we use a Lagrange multiplier \( \mu \), with the total energy being

\[
H(s) + \frac{\mu}{2} (\|s\|^2 - N)
\]

(4)

For reasons that will become clear in §4.1.1, we refer to \( \mu \) as the stability parameter. At any stationary point, the gradient and Hessian are given by

\[
\nabla H(s, \mu) = \partial H(s) + \mu s \quad \text{Hess } H(s, \mu) = \partial^2 H(s) + \mu I
\]

(5)

where \( \partial = \frac{\partial}{\partial s} \) always. An important observation was made by Bray and Dean [37] that gradient and Hessian are independent for Gaussian random functions. The average over disorder breaks into a product of two independent averages, one for any function of the gradient and one for any function of the Hessian. In particular, the number of negative eigenvalues at a stationary point, which sets the index \( I \) of the saddle, is a function of the Hessian alone (see Fyodorov [38] for a detailed discussion).

3 Equilibrium

Here we review the equilibrium solution, which has been studied in detail [39–42]. For a succinct review, see [43].

The free energy, averaged over disorder, is

\[
\beta F = -\ln \int ds \delta(\|s\|^2 - N) e^{-\beta H(s)}
\]

(6)

Once \( n \) replicas are introduced to treat the logarithm, the fields \( s_a \) can be replaced with the new \( n \times n \) matrix field \( Q_{ab} \equiv (s_a \cdot s_b)/N \). This yields for the free energy

\[
\beta F = -1 - \ln 2\pi - \frac{1}{2} \lim_{n \to 0} \frac{1}{n} \left( \beta^2 \sum_{ab} f(Q_{ab}) + \ln \det Q \right)
\]

(7)

which must be evaluated at the \( Q \) which maximizes this expression and whose diagonal is one. The solution is generally a hierarchical matrix à la Parisi. The properties of these matrices is reviewed in §A, including how to write down (7) in terms of their parameters.

The free energy can also be written in a functional form, which is necessary for working with the solution in the limit \( k \to \infty \), the so-called full replica symmetry breaking (FRSB). If \( P(q) \) is the probability distribution for elements \( q \) in a row of the matrix, then define \( \chi(q) \) by

\[
\chi(q) = \int_0^1 dq' \int_q^0 dq'' P(q''')
\]

(8)
Since it is the double integral of a probability distribution, $\chi$ must be concave, monotonically decreasing, and have $\chi(1) = 0$ and $\chi'(1) = -1$. The function $\chi$ turns out to have an interpretation as the spectrum of the hierarchical matrix $Q$. Using standard arguments, the free energy can be written as a functional over $\chi$ as

$$\beta F = -1 - \ln 2\pi - \frac{1}{2} \int_0^1 dq \left( \beta^2 f''(q) \chi(q) + \frac{1}{\chi(q)} \right)$$

which must be maximized with respect to $\chi$ given the constraints outlined above.

In our study of the landscape, the free energy will not be directly relevant anywhere except at the ground state, when the temperature is zero or $\beta \to \infty$. Here, the measure will be concentrated in the lowest minima, and the average energy $\langle E \rangle_0 = \lim_{\beta \to \infty} \frac{d}{d\beta} \beta F$ will correspond to the ground state energy $E_0$. The zero temperature limit is most easily obtained by putting $x_i = \tilde{x}_i x_k$ and $x_k = \tilde{\beta}/\beta$, $q_k = 1 - z/\beta$, which ensures the $\tilde{x}_i$, $\tilde{\beta}$, and $z$ have nontrivial limits. Inserting the ansatz and taking the limit, carefully treating the $k$th term in each sum separately from the rest, one can show after some algebra that

$$\tilde{\beta}(E)_0 = \tilde{\beta} \lim_{\beta \to \infty} \frac{\partial (\beta F)}{\partial \beta} = -\frac{1}{2} \tilde{\beta} f'(1) - \frac{1}{2} \lim_{n \to 0} \frac{1}{n} \left( \beta^2 \sum_{ab} n f(\tilde{Q}_{ab}) + \ln \det(\tilde{\beta} z^{-1} \tilde{Q} + I) \right)$$

where $\tilde{Q}$ is a $(k-1)$RSB matrix with entries $\tilde{q}_1 = \lim_{\beta \to \infty} q_1$, ..., $\tilde{q}_k-1 = \lim_{\beta \to \infty} q_{k-1}$ parameterized by $\tilde{x}_i, \ldots, \tilde{x}_{k-1}$. This is a $(k-1)$RSB ansatz whose spectrum in the determinant is scaled by $\tilde{\beta} z^{-1}$ and shifted by 1, with effective temperature $\tilde{\beta}$, and an extra term. In the continuum case, this is

$$\tilde{\beta}(E)_0 = -\frac{1}{2} \tilde{\beta} f'(1) - \frac{1}{2} \int_0^1 dq \left( \beta^2 f''(q) \tilde{\chi}(q) + \frac{1}{\tilde{\chi}(q) + \tilde{\beta} z^{-1}} \right)$$

where $\tilde{\chi}$ is bound by the same constraints as $\chi$.

The zero temperature limit of the free energy loses one level of replica symmetry breaking. Physically, this is a result of the fact that in $k$RSB, $q_k$ gives the overlap within a state, i.e., within the basin of a well inside the energy landscape. At zero temperature, the measure is completely localized on the bottom of the well, and therefore the overlap within each state becomes one. We will see that the complexity of low-energy stationary points in Kac–Rice computation is also given by a $(k-1)$RSB ansatz. Heuristically, this is because each stationary point also has no width and therefore overlap one with itself.

## 4 Landscape complexity

The stationary points of a function can be counted using the Kac–Rice formula, which integrates over the function’s domain a $\delta$-function containing the gradient multiplied by the absolute value of the determinant [44, 45]. It gives the number of stationary points $\mathcal{N}$ as

$$\mathcal{N} = \int ds \, d\mu \, \delta \left( \frac{1}{2} (|s|^2 - N) \right) \delta \left( \nabla H(s, \mu) \right) \left| \det \text{Hess} H(s, \mu) \right|$$

(12)

It is more interesting to count stationary points which share certain properties, like energy density $E$ or index density $I$. These properties can be fixed by inserting additional $\delta$-functions into the integral. Rather than fix the index directly, we fix the trace of the Hessian, which we’ll soon show is equivalent to fixing the value $\mu$, and fixing $\mu$ fixes the index to within order one. Inserting these $\delta$-functions, we arrive at

$$\mathcal{N}(E, \mu^*) = \int ds \, d\mu \, \delta \left( \frac{1}{2} (|s|^2 - N) \right) \delta \left( \nabla H(s, \mu) \right) \left| \det \text{Hess} H(s, \mu) \right|$$

$$\times \delta \left( NE - H(s) \right) \delta \left( N \mu^* - \text{Tr Hess} H(s, \mu) \right)$$

(13)

This number will typically be exponential in $N$. In order to find the typical count when disorder is averaged, we want to average its logarithm instead, which is known as the complexity:

$$\Sigma(E, \mu^*) = \lim_{N \to \infty} \frac{1}{N} \log \mathcal{N}(E, \mu^*)$$

(14)
If one averages over $N$ and afterward takes its logarithm, one arrives at the so-called annealed complexity

$$
\Sigma_a(E, \mu^*) = \lim_{N \to \infty} \frac{1}{N} \log N(E, \mu^*)
$$

(15)

The annealed complexity has been previously computed for the mixed $p$-spin models [12]. The annealed complexity is known to equal the actual (quenched) complexity in circumstances where there is at most one level of replica symmetry breaking in the model’s equilibrium. This is the case for the pure $p$-spin models, or for mixed models where $1/\sqrt{f''(q)}$ is a convex function. However, it fails dramatically for models with higher replica symmetry breaking. For instance, when $f(q) = \frac{1}{2}(q^2 + \frac{1}{3}q^3)$ (a model we study in detail later), the annealed complexity predicts that minima vanish well before the dominant saddles, a contradiction for any bounded function.

A sometimes more illuminating quantity is the Legendre transform $G$ of the complexity, defined by

$$
e^{NG(\beta, \mu^*)} = \int dE \ e^{-\beta E + \Sigma(\beta, \mu^*)}
$$

(16)

There will be a critical value $\beta_c$, beyond which the complexity is zero: above this value the measure is split between the lowest $O(1)$ energy states. We shall not study here this regime that interpolates between the dynamically relevant and the equilibrium states, but just mention that it is an interesting object of study.

### 4.1 The replicated problem

The replicated Kac–Rice formula was introduced by Ros et al. [8], and its effective action for the mixed $p$-spin model has previously been computed by Folena et al. [46]. Here we review the derivation.

In order to average the complexity over disorder, we must deal with the logarithm. We use the standard replica trick to convert the logarithm into a product, which gives

$$
\log N(E, \mu^*) = \lim_{n \to 0} \frac{\partial}{\partial n} N^n(E, \mu^*) = \lim_{n \to 0} \frac{\partial}{\partial n} \int \prod_a ds_a \ dm_\alpha \left( \delta \left( \frac{1}{2} \|s_a\|^2 - N \right) \delta(\nabla H(s_a, \mu_\alpha)) \left| \det \text{Hess} H(s_a, \mu_\alpha) \right| \right) 
$$

(17)

As discussed in §2, it has been shown that to the largest order in $N$, the Hessian of Gaussian random functions is independent from their gradient, once both are conditioned on certain properties. Here, they are only related by their shared value of $\mu$. Because of this statistical independence, we may write

$$
\Sigma(E, \mu^*) = \lim_{N \to \infty} \frac{1}{N} \lim_{n \to 0} \frac{\partial}{\partial n} \int \left( \prod_a ds_a \ dm_\alpha \right) \left( \prod_a \delta \left( \frac{1}{2} \|s_a\|^2 - N \right) \delta(\nabla H(s_a, \mu_\alpha)) \delta(NE - H(s_a)) \right) 
$$

(18)

which simplifies matters. The average of the two factors may now be treated separately.

#### 4.1.1 The Hessian factors

The spectrum of the matrix $\partial \partial H(s)$ is uncorrelated from the gradient. In the large-$N$ limit, for almost every point and realization of disorder it is a GOE matrix with variance

$$
\langle (\partial_i \partial_j H(s))^2 \rangle = \frac{1}{N} f''(1) \delta_{ij}
$$

(19)

Therefore in that limit its spectrum is given by the Wigner semicircle with radius $\sqrt{4f''(1)}$, or

$$
\rho(\lambda) = \begin{cases} 
\frac{1}{\pi} \frac{1}{4f''(1)} \sqrt{4f''(1) - \lambda^2} & \lambda^2 \leq 4f''(1) \\
0 & \text{otherwise}
\end{cases}
$$

(20)
The spectrum of the Hessian $\text{Hess}(s, \mu)$ is the same semicircle shifted by $\mu$, or $\rho(\lambda + \mu)$. The stability parameter $\mu$ thus fixes the center of the spectrum of the Hessian. The semicircle radius $\mu_m = \sqrt{4f''(1)}$ is a kind of threshold. When $\mu$ is taken to be within the range $\pm \mu_m$, the critical points have index density

$$ I(\mu) = \int_0^\infty d\lambda \rho(\lambda + \mu) = \frac{1}{2} - \frac{1}{\pi} \arctan \left( \frac{\mu}{\sqrt{\mu_m^2 - \mu^2}} \right) + \frac{\mu}{2\mu_m} \sqrt{\mu_m^2 - \mu^2} $$

(21)

When $\mu > \mu_m$, the critical points are minima whose sloppiest eigenvalue is $\mu - \mu_m$. When $\mu = \mu_m$, the critical points are marginal minima, with flat directions in their spectrum. This property of $\mu$ is why we’ve named it the stability parameter: it governs the stability of stationary points, and for unstable ones it governs its index.

To largest order in $N$, the average over the product of determinants factorizes into the product of averages, each of which is given by the same expression depending only on $\mu$ [8]. We therefore find

$$ \prod_a \left| \det \text{Hess}(s_a, \mu_a) \right| \delta(N\mu^* - \text{Tr Hess } H(s_a, \mu_a)) \rightarrow \prod_a e^{N\mathcal{D}(\mu_a)} \delta(N(\mu^* - \mu_a)) $$

(22)

where the function $\mathcal{D}$ is defined by

$$ \mathcal{D}(\mu) = \frac{1}{N} \ln \left| \det \text{Hess} H(s, \mu) \right| = \int d\lambda \rho(\lambda + \mu) \ln |\lambda| $$

$$ = \text{Re} \left\{ \frac{1}{2} \left[ 1 + \frac{\mu}{2f''(1)} (\mu - \sqrt{\mu^2 - 4f''(1)}) \right] - \ln \left( \frac{f''(1)}{2f''(1)} (\mu - \sqrt{\mu^2 - 4f''(1)}) \right) \right\} $$

(23)

By fixing the trace of the Hessian, we have effectively fixed the value of the stability $\mu$ in all replicas to the value $\mu^*$.

- For $\mu^* < \mu_m$, this amounts to fixing the index density. Since the overwhelming majority of saddles have a semicircle distribution, the fluctuations are rarer than exponential.

- For the gapped case $\mu^* > \mu_m$, there is an exponentially small probability that $r = 1, 2, \ldots$ eigenvalues detach from the semicircle in such a way that the index is in fact $N\mathcal{I} = r$. We shall not discuss these subextensive index fluctuations in this paper, the interested reader may find what is needed in [11].

### 4.1.2 The gradient factors

The $\delta$-functions in the remaining factor are treated by writing them in the Fourier basis. Introducing auxiliary fields $\tilde{s}_a$ and $\hat{\beta}$ for this purpose, for each replica replica one writes

$$ \delta\left( \frac{1}{2} \left( \|s_a\|^2 - N \right) \right) \delta(\nabla H(s_a, \mu^*)) \delta(N\xi - H(s_a)) $$

$$ = \int \frac{d\tilde{\mu}}{2\pi} \frac{d\hat{\beta}}{2\pi} \frac{ds_a}{(2\pi)^N} e^{\frac{i}{2}\tilde{\mu}(\|s_a\|^2 - N) + \hat{\beta}(\xi - H(s_a)) + is_a \cdot (\partial H(s_a) + \mu^* s_a)} $$

(24)

Anticipating a Parisi-style solution, we don’t label $\tilde{\mu}$ or $\hat{\beta}$ with replica indices, since replica vectors won’t be broken in the scheme. The average over disorder can now be taken for the pieces which depend explicitly on the Hamiltonian, and since everything is Gaussian this gives

$$ \exp \left\{ \sum_a^n \left( i\tilde{s}_a \cdot \partial_a - \hat{\beta} \right) H(s_a) \right\} = \exp \left\{ \frac{1}{2} \sum_{ab} (i\tilde{s}_a \cdot \partial_a - \hat{\beta})(i\tilde{s}_b \cdot \partial_b - \hat{\beta}) \text{H}(s_a)\text{H}(s_b) \right\} $$

$$ = \exp \left\{ \frac{N}{2} \sum_{ab} (i\tilde{s}_a \cdot \partial_a - \hat{\beta})(i\tilde{s}_b \cdot \partial_b - \hat{\beta}) f \left( \frac{s_a \cdot s_b}{N} \right) \right\} $$

$$ = \exp \left\{ \frac{N}{2} \sum_{ab} \left( \hat{\beta}^2 f \left( \frac{s_a \cdot s_b}{N} \right) - 2i\hat{\beta} \tilde{s}_a \cdot \tilde{s}_b f' \left( \frac{s_a \cdot s_b}{N} \right) + \tilde{s}_a \cdot \tilde{s}_b N f' \left( \frac{s_a \cdot s_b}{N} \right) + \tilde{s}_a \cdot \tilde{s}_b N f'' \left( \frac{s_a \cdot s_b}{N} \right) \right) \right\} $$

(25)

We introduce new matrix fields

$$ C_{ab} = \frac{1}{N} \tilde{s}_a \cdot \tilde{s}_b $$

$$ R_{ab} = -i \frac{1}{N} \tilde{s}_a \cdot \tilde{s}_b $$

$$ D_{ab} = \frac{1}{N} \tilde{s}_a \cdot \tilde{s}_b $$

(26)
Their physical meaning is explained in §9. By substituting these parameters into the expressions above and then making a change of variables in the integration from $s_a$ and $\hat{s}_a$ to these three matrices, we arrive at the form for the complexity

$$
\Sigma(E, \mu') = D(\mu') + \beta E - \frac{1}{2} \hat{\mu} + \lim_{n \to 0} \frac{1}{n} \left( \frac{1}{2} \hat{\mu} \text{Tr} C - \mu' \text{Tr} R \right) + \frac{1}{2} \sum_{ab} \left[ \hat{\beta}^2 f(C_{ab}) + (2\hat{\beta}R_{ab} - D_{ab}) f'(C_{ab}) + R^2_{ab} f''(C_{ab}) \right] + \frac{1}{2} \ln \det \begin{pmatrix} C & iR \\ iR & D \end{pmatrix}
$$

(27)

where $\hat{\mu}$, $\hat{\beta}$, $C$, $R$ and $D$ must be evaluated at the extrema of this expression which minimize the complexity. Note that one cannot minimize the complexity with respect to these parameters: there is no pure variational problem here. Extremizing with respect to $\hat{\mu}$ is not difficult, and results in setting the diagonal of $C$ to one, fixing the spherical constraint. Maintaining $\hat{\mu}$ in the complexity is useful for writing down the extremal conditions, but when convenient we will drop the dependence.

The same information is contained but better expressed in the Legendre transform

$$
G(\hat{\beta}, \mu') = D(\mu') + \lim_{n \to 0} \frac{1}{n} \left( -\mu' \text{Tr} R + \frac{1}{2} \sum_{ab} \left[ \hat{\beta}^2 f(C_{ab}) + (2\hat{\beta}R_{ab} - D_{ab}) f'(C_{ab}) + R^2_{ab} f''(C_{ab}) \right] + \frac{1}{2} \ln \det \begin{pmatrix} C & iR \\ iR & D \end{pmatrix} \right)
$$

(28)

Denoting $r_d \equiv \frac{1}{n} \text{Tr} R$, we can write down the double Legendre transform $K(\hat{\beta}, r_d)$:

$$
e^{N K(\hat{\beta}, r_d)} = \int dE d\mu' e^{N \left( \Sigma(E, \mu') - \hat{\beta} E + r_d \mu' - D(\mu') \right)}
$$

(29)

given by

$$
K(\hat{\beta}, r_d) = \lim_{n \to 0} \frac{1}{n} \left( \frac{1}{2} \sum_{ab} \left[ \hat{\beta}^2 f(C_{ab}) + (2\hat{\beta}R_{ab} - D_{ab}) f'(C_{ab}) + R^2_{ab} f''(C_{ab}) \right] + \frac{1}{2} \ln \det \begin{pmatrix} C & iR \\ iR & D \end{pmatrix} \right)
$$

(30)

where the diagonal of $C$ is fixed to one and the diagonal of $R$ is fixed to $r_d$. The variable $r_d$ is conjugate to $\mu'$ and through it to the index density, while $\hat{\beta}$ plays the role of an inverse temperature conjugate to the complexity, that has been used since the beginning of the spin-glass field. In this way $K(\hat{\beta}, r_d)$ contains all the information about saddle densities.

## 5 Replica ansatz

Based on previous work on the Sherrington–Kirkpatrick model and the equilibrium solution of the spherical model, we expect $C$, and $R$ and $D$ to be hierarchical matrices in Parisi’s scheme. This assumption immediately simplifies the extremal conditions, since hierarchical matrices commute and are closed under matrix products and Hadamard products. In particular, the determinant of the block matrix can be written as a determinant of a product,

$$\ln \det \begin{pmatrix} C & iR \\ iR & D \end{pmatrix} = \ln \det(CD + R^2)
$$

(31)

This is straightforward (if strenuous) to write down at $k$RSB, since the product and sum of the hierarchical matrices is still a hierarchical matrix. The algebra of hierarchical matrices is reviewed in §A. Using the product formula (95), one can write down the hierarchical matrix $CD + R^2$, and then compute the $\ln \det$ using the formula (94).
The extremal conditions are given by differentiating the complexity with respect to its parameters, yielding

\[ 0 = \frac{\partial \Sigma}{\partial \hat{\mu}} = \frac{1}{2} (c_d - 1) \]  
\[ 0 = \frac{\partial \Sigma}{\partial \hat{\beta}} = E + \lim_{n \to \infty} \frac{1}{n} \sum_{ab} [\hat{\beta} f(C_{ab}) + R_{ab} f'(C_{ab})] \]  
\[ 0 = \frac{\partial \Sigma}{\partial C} = \frac{1}{2} \left[ \hat{\mu} I + \hat{\beta} f'(C) + (2 \hat{\beta} R - D) \odot f''(C) + R \odot R \odot f'''(C) + (CD + R^2)^{-1} D \right] \]  
\[ 0 = \frac{\partial \Sigma}{\partial R} = -\hat{\mu}' I + \hat{\beta} f'(C) + R \odot f''(C) + (CD + R^2)^{-1} R \]  
\[ 0 = \frac{\partial \Sigma}{\partial D} = -\frac{1}{2} f'(C) + \frac{1}{2} (CD + R^2)^{-1} C \]  

where \( \odot \) denotes the Hadamard product, or the componentwise product. Equation (36) implies that

\[ D = f'(C)^{-1} - RC^{-1}R \]  

To these conditions must be added the addition condition that \( \Sigma \) is extremal with respect to \( x_1, \ldots, x_k \). There is no better way to enforce this condition than to directly differentiate \( \Sigma \) with respect to the \( x \)s, and we have

\[ 0 = \frac{\partial \Sigma}{\partial x_i} \quad 1 \leq i \leq k \]  

The stationary conditions for the \( x \)s are the most numerically taxing. In addition to these equations, we often want to maximize the complexity as a function of \( \mu^* \), to find the most common type of stationary points. These are given by the condition

\[ 0 = \frac{\partial \Sigma}{\partial \mu^*} = \mathcal{D}'(\mu^*) - r_d \]  

Since \( \mathcal{D}(\mu^*) \) is effectively a piecewise function, with different forms for \( \mu^* \) greater or less than \( \mu_m \), there are two regimes. When \( \mu^* > \mu_m \) and the critical points are minima, (39) implies

\[ \mu^* = \frac{1}{r_d} + r_d f''(1) \]  

When \( \mu^* < \mu_m \) and the critical points are saddles, it implies

\[ \mu^* = 2 f''(1) r_d \]  

It is often useful to have the extremal conditions in a form without matrix inverses, so that the saddle conditions can be expressed using products alone. By simple manipulations, the matrix equations can be written as

\[ 0 = [\hat{\beta}^2 f'(C) + (2 \hat{\beta} R - D) \odot f''(C) + R \odot R \odot f'''(C) + \hat{\mu} I] C + f'(C) D \]  
\[ 0 = [\hat{\beta} f'(C) + R \odot f''(C) - \mu^* I] C + f'(C) R \]  
\[ 0 = C - f'(C)(CD + R^2) \]

The right-hand side of each of these equations is also a hierarchical matrix, since products, Hadamard products, and sums of hierarchical matrices are such.

6 Supersymmetric solution

The Kac–Rice problem has an approximate supersymmetry, which is found when the absolute value of the determinant is neglected and the trace of the Hessian is not fixed. This supersymmetry has been studied in great detail in the complexity of the Thouless–Anderson–Palmer (TAP) free energy [47–51]. When the absolute value is dropped, the determinant in (12) can be represented by an integral over Grassmann variables, which yields a complexity depending on ‘bosons’ and ‘fermions’ that share the supersymmetry. The Ward identities associated
with the supersymmetry imply that $D = \beta R$ [47]. Under which conditions can this relationship be expected to hold? We find that their applicability is limited to a specific line in the energy and stability plane.

The identity $D = \beta R$ heavily constrains the form that the rest of the solution can take. Assuming the supersymmetry holds, (34) implies

$$0 = \hat{\mu}I + \hat{\beta}^2 f'(C) + \beta R \odot f''(C) + R \odot R \odot f'''(C) + \hat{\beta}(CD + R^2)^{-1}R$$

(45)

Substituting (35) for the factor $(CD + R^2)^{-1}R$, we find substantial cancellation, and finally

$$0 = (\hat{\mu} + \mu^r)I + R \odot R \odot f''(C)$$

(46)

If $C$ has a nontrivial off-diagonal structure and supersymmetry holds, then the off-diagonal of $R$ must vanish, and therefore $R = r_d I$. Therefore, a supersymmetric ansatz is equivalent to a diagonal ansatz for both $R$ and $D$.

Supersymmetry has further implications. Equations (35) and (36) can be combined to find

$$I = R \left[ \mu^r I - R \odot f''(C) \right] + (D - \beta R)f'(C)$$

(47)

Assuming the supersymmetry holds implies that

$$I = R \left[ \mu^r I - R \odot f''(C) \right]$$

(48)

Understanding that $R$ is diagonal, we find

$$\mu^r = \frac{1}{r_d} + r_d f''(1)$$

(49)

which is precisely the condition (40) for dominant minima. Therefore, the supersymmetric solution counts the most common minima [49]. When minima are not the most common type of stationary point, the supersymmetric solution correctly counts minima that satisfy (40), but these do not have any other special significance.

Inserting the supersymmetric ansatz $D = \beta R$ and $R = r_d I$, one gets for the complexity

$$\Sigma(E, \mu^r) = D(\mu^r) + \beta E - \mu^r r_d + \frac{1}{2} \beta r_d f'(1) + \frac{1}{2} r_d^2 f''(1) + \frac{1}{2} \ln r_d^2$$

$$+ \frac{1}{2} \lim_{n \to 0} \frac{1}{n} \left( \beta^2 \sum_{ab} f(C_{ab}) + \ln \text{det}(\beta r_d C + I) \right)$$

(50)

From here, it is straightforward to see that the complexity vanishes at the ground state energy. First, in the ground state minima will dominate (even if they are marginal), so we may assume (40). Then, taking $\Sigma(E_0, \mu^r) = 0$, gives

$$\beta E_0 = -\frac{1}{2} r_d \beta f'(1) - \frac{1}{2} \lim_{n \to 0} \frac{1}{n} \left( \beta^2 \sum_{ab} f(C_{ab}) + \ln \text{det}(\beta r_d C + I) \right)$$

(51)

which is precisely the ground state energy predicted by the equilibrium solution (10) with $r_d = z$, $\hat{\beta} = \beta$, and $C = Q$.

Therefore a $(k - 1)$RSB ansatz in Kac–Rice will predict the correct ground state energy for a model whose equilibrium state at small temperatures is $k$RSB Moreover, there is an exact correspondence between the saddle parameters of each. If the equilibrium is given by a Parisi matrix with parameters $x_1, \ldots, x_k$ and $q_1, \ldots, q_k$, then the parameters $\hat{\beta}, r_d, d_d, \tilde{x}_1, \ldots, \tilde{x}_{k-1}$, and $c_1, \ldots, c_{k-1}$ for the complexity in the ground state are

$$\hat{\beta} = \lim_{\tilde{\beta} \to \infty} \beta x_k$$

$$\tilde{x}_i = \lim_{\tilde{\beta} \to \infty} \frac{x_i}{x_k}$$

$$c_i = \lim_{\tilde{\beta} \to \infty} q_i$$

$$r_d = \lim_{\tilde{\beta} \to \infty} \beta (1 - q_k)$$

$$d_d = \hat{\beta} r_d$$

(52)

Unlike the case for the TAP complexity, this correspondence between landscape complexity and equilibrium solutions only exists at the ground state. We will see in our examples in §8 that there appears to be little correspondence between these parameters away from the ground state.

The supersymmetric solution produces the correct complexity for the ground state and for a class of minima, including dominant ones. Moreover, it produces the correct parameters for the fields $C$, $R$, and $D$ at those points. This is an important foothold in the problem of computing the general complexity. The full saddle point equations at $k$RSB are not very numerically stable, and a ‘good’ saddle point has a typically small radius of convergence under methods like Newton’s algorithm. With the supersymmetric solution in hand, it is possible to take small steps in the parameter space to find non-supersymmetric numeric solutions, each time ensuring the initial conditions for the solver are sufficiently close to the correct answer. This is the strategy we use in §8.
7 Full replica symmetry breaking

This reasoning applies equally well to FRSB systems. In the end, when the limit of \( n \to 0 \) is taken, each matrix field can be represented in the canonical way by its diagonal and a continuous function on the domain \([0, 1]\) which parameterizes each of its rows, with

\[
C \leftrightarrow [c_d, c(x)] \quad R \leftrightarrow [r_d, r(x)] \quad D \leftrightarrow [d_d, d(x)]
\]  

The algebra of hierarchical matrices under this continuous parameterization is reviewed in §A. With these substitutions, the complexity becomes

\[
\Sigma(E, \mu^*) = D(\mu^*) + \beta E - r_d^\mu + \frac{1}{2} \left[ \beta^2 f'(1) + (2\beta r_d - d_d) f'(1) + r_d^2 f''(1) \right] - \frac{1}{2} \int_0^1 dx \left[ \beta^2 f(c(x)) + (2\beta r(x) - d(x)) f'(c(x)) + r(x) f''(c(x)) \right] + \frac{1}{2} \lim_{n \to 0} \ln \det(\text{CD} + R^2)
\]  

The formula for the determinant is complicated, and can be found by using the product formula (98) to write \( CD \) and \( R^2 \), summing them, and finally using the \( \ln \det \) formula (101). The saddle point equations take the form

\[
0 = \mu c(x) + \left( \beta^2 (f' \circ c) + (2\beta r - d)(f'' \circ c) + r^2 (f''' \circ c) \right) \ast c(x) + \left( (f' \circ c) \ast d \right)(x)
\]

\[
0 = -\mu^* c(x) + \left( \beta^2 (f' \circ c) + r (f'' \circ c) \right) \ast c(x) + \left( (f' \circ c) \ast r \right)(x)
\]

\[
0 = c(x) - \left( (f' \circ c) \ast (c \ast d + r) \right)(x)
\]

where \((ab)(x) = a(x)b(x)\) denotes the hadamard product, \((a \ast b)(x)\) denotes the functional parameterization of the diagonal of the product of hierarchical matrices \( AB \) defined in (98), and \((a \circ b)(x) = a(b(x))\) denotes composition.

7.1 Supersymmetric complexity

Using standard manipulations, one finds also a continuous version of the supersymmetric complexity

\[
\Sigma(E, \mu^*) = D(\mu^*) + \beta E - r_d^\mu + \frac{1}{2} \left( \beta r_d f'(1) + r_d^2 f''(1) + \ln r_d^2 \right) + \frac{1}{2} \int_0^1 dq \left( \beta^2 f''(q) \chi(q) + \frac{1}{\chi(q) + r_d/\beta} \right)
\]

where \(\chi(q) = \int_0^q dq' \hat{f}'(q') \text{d}q' P(q)\) for \(P(q)\) the distribution of elements in a row of \( C \), as in the equilibrium case. Like in the equilibrium case, \(\chi\) must be concave, monotonically decreasing, and have \(\chi(1) = 0\), \(\chi'(1) = -1\).

First, we use this solution to inspect the ground state of a full RSB system. We know from the equilibrium that in the ground state \(\chi\) is continuous in the whole range of \( q \). Therefore, the saddle solution found by extremizing

\[
0 = \frac{\delta \Sigma}{\delta \chi(q)} = \frac{\beta^2}{2} f''(q) - \frac{1}{2} \left( \chi(q) + r_d/\beta \right)^2
\]

over all functions \(\chi\). This gives

\[
\chi_0(q \mid \hat{\beta}, r_d) = \frac{1}{\beta} \left( f''(q)^{-1/2} - r_d \right)
\]

Satisfying the boundary conditions requires \(r_d = f''(1)^{-1/2}\) and \(\hat{\beta} = \frac{1}{\beta} f'''(1)/f''(1)^{3/2}\). This in turn implies \(\mu^* = \frac{1}{\beta} + f''(1)r_d = \sqrt{4f''(1)} = \mu_m\). Therefore, the FRSB ground state is always marginal, as excepted. It is straightforward to check that these conditions are indeed a saddle of the complexity. This has several implications. First, other than the ground state, there are no energies at which minima are most numerous; saddles always dominate. As we will see, stable minima are numerous at energies above the ground state, but these vanish at the ground state.

Away from the ground state, this expression still correctly counts a class of non-dominant minima. However, like in the equilibrium solution, the function \(\chi\) which produces an extremal value is not smooth in the entire range \([0, 1]\), but adopts a piecewise form

\[
\chi(q) = \begin{cases} 
\chi_0(q \mid \hat{\beta}, r_d) & q \leq q_{\text{max}} \\
1 - q & \text{otherwise}
\end{cases}
\]
With this ansatz, the complexity must be extremized with respect to \( \hat{\beta} \) and \( \hat{\beta} \), while simultaneously ensuring that \( q_{\text{max}} \) is such that \( \chi(q) \) is continuous, that is, that \( \chi(0, q_{\text{max}} | \hat{\beta}, r_d) = 1 - q_{\text{max}} \). The significance of the minima counted by this method is unclear, but they do represent a nodal line in the off-diagonal parts of \( R \) and \( D \). Since, as usual, \( \chi(q) \) is related to \( c(x) \) by \(-\chi'(c(x)) = x\), there is a corresponding \( x_{\text{max}} \) given by:

\[
x_{\text{max}} = -\chi'(q_{\text{max}}) = \frac{1}{2\hat{\beta}} \frac{f'''(q_{\text{max}})}{f''(q_{\text{max}})^{3/2}}
\]

### 7.2 Expansion near the transition

Working with the continuum equations away from the supersymmetric solution is not generally tractable. However, there is another point where they can be treated analytically: near the onset of replica symmetry breaking. Here, the off-diagonal components of \( C \), \( R \), and \( D \) are expected to be small. In particular, we expect the functions \( c(x) \), \( r(x) \), and \( d(x) \) to approach zero at the transition, and moreover take the piecewise linear form:

\[
c(x) = \begin{cases} \hat{c}x & x \leq x_{\text{max}} \\ \bar{c}x & x > x_{\text{max}} \end{cases} \\
r(x) = \begin{cases} \hat{r}x & x \leq x_{\text{max}} \\ \bar{r}x & x > x_{\text{max}} \end{cases} \\
d(x) = \begin{cases} \hat{d}x & x \leq x_{\text{max}} \\ \bar{d}x & x > x_{\text{max}} \end{cases}
\]

with \( x_{\text{max}} \) vanishing at the transition, with the slopes \( \hat{c} \), \( \hat{r} \), and \( \hat{d} \) remaining nonzero. This ansatz is informed both by the experience of the equilibrium solution, and by empirical observation within the numerics of §8.

Given this ansatz, we take the equations (55), (56), and (57), which are true for any \( x \), and integrate them over \( x \). We then expand the result about small \( x_{\text{max}} \) to linear order in \( x_{\text{max}} \). Equation (56) depends linearly on \( \hat{r} \) to all orders, and therefore \( \hat{r} \) can be found in terms of \( \bar{c} \), yielding:

\[
\frac{\hat{r}}{\bar{c}} = -\hat{\beta} - \frac{1}{f'(1) + f''(0)}(r_d f''(0) + f''(1) - \mu^*) + O(x_{\text{max}})
\]

Likewise, (57) depends linearly on \( \hat{d} \) to all orders, and can be solved to give:

\[
\frac{\hat{d}}{\bar{c}} = -2r_d \frac{\hat{r}}{\bar{c}} - \frac{1}{f'(1)}(r_d^2 f''(0) + d_d f''(1) + f''(0) - 1) + O(x_{\text{max}})
\]

The equations cannot be used to find the value of \( \bar{c} \) without going to higher order in \( x_{\text{max}} \), but the transition line can be determined by examining the stability of the replica symmetric complexity. First, we expand the full form for the complexity about small \( x_{\text{max}} \) in the same way as we expand the extremal conditions, using (101) to treat the determinant. To quadratic order, this gives:

\[
\Sigma(E, \mu^*) = \mathcal{D}(\mu^*) + \hat{\beta}E - \mu r_d + \frac{1}{2} \left[ \hat{\beta}^2 f(1) + (2\hat{\beta} r_d - d_d) f'(1) + r_d^2 f''(1) \right] + \frac{1}{2} \ln(\hat{\beta} + r_d^2)
\]

\[
\Sigma(E, \mu^*) = -\frac{1}{2} \left[ \hat{\beta}^2 \bar{c}^2 f''(0) + (2\hat{\beta}\hat{r} - \hat{d})\bar{c} f''(0) + \hat{r}^2 f''(0) - \frac{\bar{d}^2 - 2d_d \hat{r}^2 + d_d^2 c_d^2 + 4r_d \hat{r} (\hat{d} + d_d \hat{c}) - 2r_d^2 (\hat{c} \hat{d} + \bar{c}^2)}{2(d_d + r_d^2)^2} \right] \bar{c}^2 x_{\text{max}}^2
\]

The spectrum of the Hessian of \( \Sigma \) with evaluated at the RS solution gives its stability with respect to these functional perturbations. When the values of \( \hat{r} \) and \( \hat{d} \) above are substituted into the Hessian and \( \hat{\beta}, r_d \), and \( d_d \) are evaluated at their RS values, the eigenvalue of interest takes the form:

\[
\lambda = -\bar{c}^2 \left( \frac{(f'(1) - 2f(1))^2 f'(1) - f''(0)) f''(0)}{2(f'(1) + f''(0))(f'(1)^2 - f(1)(f'(1) + f''(1)))^2} (\mu^* - \mu_+^*(E)) (\mu^* - \mu_-^*(E)) \right)
\]

where

\[
\mu_+^*(E) = \pm \left( \frac{(f'(1) + f''(0))(f'(1)^2 - f(1)(f'(1) + f''(0)))}{(2f(1) - f'(1))(f'(1) f''(0)^{0.1/2})} - \frac{f''(1) - f'(1)}{f'(1) - 2f(1)} E \right)
\]

This eigenvalue changes sign when \( \mu^* \) crosses \( \mu_+^*(E) \). We expect that this is the line of stability for the replica symmetric solution when the transition is RS-FRSB. The numerics in §8 bear this out.
8 General solution: examples

Though we have only written down an easily computable complexity along a specific (and often uninteresting) line in energy and stability, this computable (supersymmetric) solution gives a numeric foothold for computing the complexity in the rest of that space. First, (11) is maximized with respect to its parameters, since the equilibrium solution is equivalent to a variational problem. Second, the mapping (52) is used to find the corresponding Kac–Rice saddle parameters in the ground state. With these parameters in hand, small steps are then made in energy $E$ or stability $\mu$, after which known these values are used as the initial condition for a saddle-finding problem. In this section, we use this basic numeric idea to map out the complexity for two representative examples: a model with a 2RSB equilibrium ground state and therefore 1RSB complexity in its vicinity, and a model with a FRSB equilibrium ground state, and therefore FRSB complexity as well.

8.1 1RSB complexity

It is known that by choosing a covariance $f$ as the sum of polynomials with well-separated powers, one develops 2RSB in equilibrium. This should correspond to 1RSB in Kac–Rice. For this example, we take

$$f(q) = \frac{1}{2} \left( q^3 + \frac{1}{16} q^{16} \right)$$

established to have a 2RSB ground state [52]. With this covariance, the model sees a replica symmetric to 1RSB 2RSB in equilibrium. This should correspond to 1RSB in Kac–Rice. For this example, we take

It is known that by choosing a covariance $f$ as the sum of polynomials with well-separated powers, one develops 2RSB in equilibrium. This should correspond to 1RSB in Kac–Rice. For this example, we take

$$f(q) = \frac{1}{2} \left( q^3 + \frac{1}{16} q^{16} \right)$$

established to have a 2RSB ground state [52]. With this covariance, the model sees a replica symmetric to 1RSB transition at $\beta_1 = 1.70615 \ldots$ and a 1RSB to 2RSB transition at $\beta_2 = 6.02198 \ldots$. At these transitions, the average energies in equilibrium are $(E)_1 = -0.906391 \ldots$ and $(E)_2 = -1.19553 \ldots$, respectively, and the ground state energy is $E_0 = -1.287605530 \ldots$. Besides these typical equilibrium energies, an energy of special interest for looking at the landscape topology is the algorithmic threshold $E_{\text{alg}}$, defined by the lowest energy reached by local algorithms like approximate message passing [53, 54]. In the spherical models, this has been proven to be

$$E_{\text{alg}} = -\int_0^1 dq \sqrt{f''(q)}$$

For full RSB systems, $E_{\text{alg}} = E_0$ and the algorithm can reach the ground state energy. For the pure $p$-spin models, $E_{\text{alg}} = E_{\text{th}}$, where $E_{\text{th}}$ is the energy at which marginal minima are the most common stationary points. Something about the topology of the energy function might be relevant to where this algorithmic threshold lies. For the $3+16$ model at hand, $E_{\text{alg}} = -1.275140128 \ldots$.

In this model, the RS complexity gives an inconsistent answer for the complexity of the ground state, predicting that the complexity of minima vanishes at a higher energy than the complexity of saddles, with both at a lower energy than the equilibrium ground state. The 1RSB complexity resolves these problems, predicting the same ground state as equilibrium and with a ground state stability $\mu_0 = 6.480764 \ldots > \mu_{\text{th}}$. It predicts that the complexity of marginal minima (and therefore all saddles) vanishes at $E_{\text{th}} = -1.287605527 \ldots$, which is very slightly greater than $E_0$. Saddles become dominant over minima at a higher energy $E_{\text{th}} = -1.287575114 \ldots$. The 1RSB complexity transitions to a RS description for dominant stationary points at an energy $E_1 = -1.273886852 \ldots$. The highest energy for which the 1RSB description exists is $E_{\text{max}} = -0.886029051 \ldots$.

The complexity as a function of energy difference from the ground state is plotted in Fig. 1. In that figure, the complexity is plotted for dominant minima and saddles, marginal minima, and supersymmetric minima. A contour plot of the complexity as a function of energy $E$ and stability $\mu$ is shown in Fig. 2. That plot also shows the RS–1RSB transition line in the complexity. For minima, the complexity does not inherit a 1RSB description until the energy is with in a close vicinity of the ground state. On the other hand, for high-index saddles the complexity becomes described by 1RSB at quite high energies. This suggests that when sampling a landscape at high energies, high index saddles may show a sign of replica symmetry breaking when minima or inherent states do not.

Fig. 3 shows a different detail of the complexity in the vicinity of the ground state, now as functions of the energy difference and stability difference from the ground state. Several of the landmark energies described above are plotted, alongside the boundaries between the ‘phases.’ Though $E_{\text{alg}}$ looks quite close to the energy at which dominant saddles transition from 1RSB to RS, they differ by roughly $10^{-3}$, as evidenced by the numbers cited above. Likewise, though $(E)_1$ looks very close to $E_{\text{max}}$, where the 1RSB transition line terminates, they too differ. The fact that $E_{\text{alg}}$ is very slightly below the place where most saddle transition to 1RSB is suggestive; we speculate that an analysis of the typical minima connected to these saddles by downward trajectories will coincide with the algorithmic limit. An analysis of the typical nearby minima or the typical downward trajectories from these saddles
Figure 1: Complexity of dominant saddles (blue), marginal minima (yellow), and dominant minima (green) of the $3 + 16$ model. Solid lines show the result of the 1RSB ansatz, while the dashed lines show that of a RS ansatz. The complexity of marginal minima is always below that of dominant critical points except at the black dot, where they are dominant. The inset shows a region around the ground state and the fate of the RS solution.

Figure 2: Complexity of the $3 + 16$ model in the energy $E$ and stability $\mu^*$ plane. The right shows a detail of the left. Below the yellow marginal line the complexity counts saddles of increasing index as $\mu^*$ decreases. Above the yellow marginal line the complexity counts minima of increasing stability as $\mu^*$ increases.
Figure 3: Detail of the ‘phases’ of the 3 + 16 model complexity as a function of energy and stability. Above the yellow marginal stability line the complexity counts saddles of fixed index, while below that line it counts minima of fixed stability. The shaded red region shows places where the complexity is described by the 1RSB solution, while the shaded gray region shows places where the complexity is described by the RS solution. In white regions the complexity is zero. Several interesting energies are marked with vertical black lines: the traditional ‘threshold’ $E_{\text{th}}$ where minima become most numerous, the algorithmic threshold $E_{\text{alg}}$ that bounds the performance of smooth algorithms, and the average energies at the 2RSB and 1RSB equilibrium transitions $\langle E \rangle_2$ and $\langle E \rangle_1$, respectively.

Though the figure is suggestive, $E_{\text{alg}}$ lies at slightly lower energy than the termination of the RS – 1RSB transition line.

at 1RSB is warranted [8, 55]. Also notable is that $E_{\text{alg}}$ is at a significantly higher energy than $E_{\text{th}}$; according to the theory, optimal smooth algorithms in this model stall in a place where minima are exponentially subdominant.

Fig. 4 shows the saddle parameters for the 3 + 16 system for notable species of stationary points, notably the most common, the marginal ones, those with zero complexity, and those on the transition line. When possible, these are compared with the same expressions in the equilibrium solution at the same average energy. Besides the agreement at the ground state energy, there seems to be little correlation between the equilibrium and complexity parameters.

Of specific note is what happens to $d_1$ as the 1RSB phase boundary for the complexity meets the zero complexity line. Here, $d_1$ diverges like

$$d_1 = -\left(\frac{1}{f'(1)} - (d_d + r_d^2)\right) (1 - x_1)^{-1} + O(1)$$

(71)

while $x_1$ and $q_1$ both go to one. Note that this is the only place along the phase boundary where $q_1$ goes to one. The significance of this critical point in the complexity of high-index saddles is worth further study.

### 8.2 Full RSB complexity

If the covariance $f$ is chosen to be concave, then one develops FRSB in equilibrium. To this purpose, we choose

$$f(q) = \frac{1}{2} \left(q^2 + \frac{1}{16} q^4\right)$$

(72)

also studied before in equilibrium [41, 42]. Because the ground state is FRSB, for this model

$$E_0 = E_{\text{alg}} = E_{\text{th}} = -\int_0^1 dq \sqrt{f''(q)} = -1.059 \ 384 \ 319 \ldots$$

(73)

In the equilibrium solution, the transition temperature from RS to FRSB is $\beta_{\infty} = 1$, with corresponding average energy $\langle E \rangle_{\infty} = -0.53125 \ldots$
Along the supersymmetric line, the FRSB solution can be found in full, exact functional form. To treat the FRSB away from this line numerically, we resort to finite kRSB approximations. Since we are not trying to find the actual kRSB solution, but approximate the FRSB one, we drop the extremal condition (38) for $x_1, \ldots, x_k$ and instead set

$$x_i = \left( \frac{i}{k+1} \right) x_{\text{max}}$$

and extremize over $x_{\text{max}}$ alone. This dramatically simplifies the equations that must be solved to find solutions. In the results that follow, a 20RSB approximation is used to trace the dominant saddles and marginal minima, while a 5RSB approximation is used to trace the (much longer) boundaries of the complexity.

Fig. 5 shows the complexity for this model as a function of energy difference from the ground state for several notable trajectories in the energy and stability plane. Fig. 6 shows these trajectories, along with the phase boundaries of the complexity in this plane. Notably, the phase boundary predicted by (68) correctly predicts where all of the finite kRSB approximations terminate. Like the 1RSB model in the previous subsection, this phase boundary is oriented such that very few, low energy, minima are described by a FRSB solution, while relatively high energy saddles of high index are also. Again, this suggests that studying the mutual distribution of high-index saddle points might give insight into lower-energy symmetry breaking in more general contexts.

Fig. 7 shows the value of $x_{\text{max}}$ along several trajectories of interest. Everywhere along the transition line, $x_{\text{max}}$ continuously goes to zero. Examples of our 20RSB approximations of the continuous functions $c(x)$, $r(x)$, and $d(x)$ are also shown. As expected, these functions approach linear ones as $x_{\text{max}}$ goes to zero with finite slopes.

## 9 Interpretation

Let $\langle A \rangle$ be the average of any function $A$ over stationary points with given $E$ and $\mu^*$, i.e.,

$$\langle A \rangle = \frac{1}{N} \sum_{s \in S} A(s) = \frac{1}{N} \int dv(s) A(s)$$

with

$$dv(s) = ds \, d\mu \, \delta \left( \frac{1}{2} (||s||^2 - N) \right) \delta (\nabla H(s, \mu)) \left| \det \text{Hess} \, H(s, \mu) \right| \delta (NE - H(s)) \delta (N\mu^* - \text{Tr Hess} \, H(s, \mu))$$

(Figures 4, 5, 6, 7)
Figure 5: The complexity $\Sigma$ of the mixed $2+4$ spin model as a function of distance $\Delta E = E - E_0$ of the ground state. The solid blue line shows the complexity of dominant saddles given by the FRSB ansatz, and the solid yellow line shows the complexity of marginal minima. The dashed lines show the same for the annealed complexity. The inset shows more detail around the ground state.

Figure 6: ‘Phases’ of the complexity for the $2+4$ model in the energy $E$ and stability $\mu^*$ plane. The region shaded gray shows where the RS solution is correct, while the region shaded red shows that where the FRSB solution is correct. The white region shows where the complexity is zero.
Figure 7: $x_{\text{max}}$ as a function of $E$ for several trajectories of interest, along with examples of the 20RSB approximations of the functions $c(x)$, $r(x)$, and $d(x)$ along the dominant saddles. Colors of the approximate functions correspond to the points on the $x_{\text{max}}$ plot. The supersymmetric line terminates where the complexity reaches zero, which happens inside the FRSB phase.
the Kac–Rice measure. Note that this definition of the angle brackets, which is in analogy with the typical equilibrium average, is not the same as that used in §7.2 for averaging over the off-diagonal elements of a hierarchical matrix. The fields $C$, $R$, and $D$ defined in (26) can be related to certain averages of this type.

### 9.1 C: distribution of overlaps

First consider $C$, which has an interpretation nearly identical to that of Parisi’s $Q$ matrix of overlaps in the equilibrium case. Its off-diagonal corresponds to the probability distribution $P(q)$ of the overlaps $q = (s_1 \cdot s_2)/N$ between stationary points. Let $\mathcal{S}$ be the set of all stationary points with given energy density and index. Then

$$P(q) \equiv \frac{1}{N^2} \sum_{s_1, s_2} \delta \left( \frac{s_1 \cdot s_2}{N} - q \right)$$

This is the probability that two stationary points uniformly drawn from the ensemble of all stationary points with fixed energy and index.

The moments of this distribution $q^{(p)}$ are given by

$$q^{(p)} \equiv \int_0^1 dq \, q^p P(q) = \frac{1}{N^p} \sum_{i_1 \cdots i_p} \langle s_{i_p} \cdots s_{i_1} \rangle (s_{i_1} \cdots s_{i_p}) = \frac{1}{N^p} \quad \frac{1}{N^2} \sum_{s_1, s_2, i_1 \cdots i_p} s_{i_1}^1 \cdots s_{i_p}^1 s_{i_1}^2 \cdots s_{i_p}^2$$

The $(n-2)$ extra replicas provide the normalization, with $\lim_{n \to 0} N^{n-2} = N^{-2}$. Replacing the sums over stationary points with integrals over the Kac–Rice measure, the average over disorder (again, for fixed energy and index) gives

$$\overline{q^{(p)}} = \frac{1}{N^p} \sum_{i_1 \cdots i_p} \langle s_{i_p} \cdots s_{i_1} \rangle (s_{i_1} \cdots s_{i_p}) = \lim_{n \to 0} \int D \{C, R, D\} \, e^{nN\Sigma[C,R,D]} \frac{1}{n(n-1)} \sum_{a \neq b} (C_{ab})^p \, e^{nN\Sigma[C,R,D]}$$

In the last line, we have used that there is nothing special about replicas one and two. Using the Parisi ansatz, evaluating by saddle point summing over all the $n(n-1)$ saddles related by permutation we then have

$$\overline{q^{(p)}} = \int_0^1 dx \, e^p (x) = \int_0^1 dq \, q^p P(q)$$

concluding $P(q) = \frac{dx}{dq} = \left( \frac{dx}{dq} \right)^{-1}_{c(x)=q}$  

The appeal of Parisi to properties of pure states is unnecessary here, since the stationary points are points.

With this established, we now address what it means for $C$ to have a nontrivial replica-symmetry broken structure. When $C$ is replica symmetric, drawing two stationary points at random will always lead to the same overlap. In the case when there is no linear field and $q_0 = 0$, they will always have overlap zero, because the second point will almost certainly lie on the equator of the sphere with respect to the first. Though other stationary points exist nearby the first one, they are exponentially fewer and so will be picked with vanishing probability in the thermodynamic limit.

When $C$ is replica-symmetry broken, there is a nonzero probability of picking a second stationary point at some other overlap. This can be interpreted by imagining the level sets of the Hamiltonian in this scenario. If the level sets are disconnected but there are exponentially many of them distributed on the sphere, one will still find zero average overlap. However, if the disconnected level sets are few, i.e., less than order $N$, then it is possible to draw two stationary points from the same set with nonzero probability. Therefore, the picture in this case is of few large basins each containing exponentially many stationary points. A cartoon of this picture is shown in Fig. 8.
Figure 8: A cartoon visualizing how to interpret replica symmetry breaking solutions in the complexity. The black region show schematically areas where stationary points of a given energy can be found. Left: When the region is connected, pairs of stationary points exist at any overlap, but the vast majority of pairs are orthogonal. Center: When there are exponentially many disconnected regions of similar size, the vast majority of pairs will be found in different, orthogonal regions. Right: When there are a few large disconnected regions, pairs have a comparable probability to be found in different regions or in the same region. This gives rise to two (or more) possible overlaps.

9.1.1 A tractable example

One can construct a schematic 2RSB model from two 1RSB models. Consider two independent pure models of size $N$ and with $p_1$-spin and $p_2$-spin couplings, respectively, with energies $H_{p_1}(s)$ and $H_{p_2}(\sigma)$, and couple them weakly with $\varepsilon \cdot \sigma \cdot s$. The landscape of the pure models is much simpler than that of the mixed because, in these models, fixing the stability $\mu$ is equivalent to fixing the energy: $\mu = pE$. This implies that at each energy level there is only one type of stationary point. Therefore, for the pure models our formulas for the complexity and its Legendre transforms are functions of one variable only, $E$, and each instance of $\mu^*$ inside must be replaced with $pE$.

In the joint model, we wish to fix the total energy, not the energies of the individual two models. Therefore, we insert a $\delta$-function containing $(E_1 + E_2) - E$ and integrate over $E_1$ and $E_2$. This results in a joint complexity (and Legendre transform)

$$e^{N\Sigma(E)} = \int dE_1 dE_2 d\lambda \exp \left\{ N \left[ \Sigma_1(E_1) + \Sigma_2(E_2) + O(\varepsilon) - \lambda \left( (E_1 + E_2) - E \right) \right] \right\}$$  \hspace{1cm} (81)

$$e^{N\Sigma(\hat{\beta})} = \int dE dE_1 dE_2 d\lambda \exp \left\{ N \left[ -\hat{\beta}E + \Sigma_1(E_1) + \Sigma_2(E_2) + O(\varepsilon) - \lambda \left( (E_1 + E_2) - E \right) \right] \right\}$$  \hspace{1cm} (82)

The saddle point is given by $\Sigma_1'(E_1) = \Sigma_2'(E_2) = \hat{\beta}$, provided that both $\Sigma_1(E_1)$ and $\Sigma_2(E_2)$ are non-zero. In this situation, two systems are ‘thermalized’, and, because many points contribute, the overlap between two global configurations is zero:

$$\frac{1}{2N} \left( \langle s^1 \cdot \sigma^1 \rangle \cdot \langle s^2 \cdot \sigma^2 \rangle \right) = \frac{1}{2N} \left| \langle s^1 \cdot s^2 \rangle + \langle \sigma^1 \cdot \sigma^2 \rangle \right| = 0$$  \hspace{1cm} (83)

This is the ‘annealed’ phase of a Kac-Rice calculation.

Now start going down in energy, or up in $\hat{\beta}$: there will be a point $E_c$ or $\hat{\beta}_c$ at which one of the subsystems (say it is system one) freezes at its lowest energy density, while system two is not yet frozen. At this point, $\Sigma_1(E_1) = 0$ and $E_1$ is the ground state energy. At an even higher value $\hat{\beta} = \hat{\beta}_f$, both systems will become frozen in their ground states. For $\hat{\beta}_f > \hat{\beta} > \hat{\beta}_c$ one system is unfrozen, while the other is, because of coupling, frozen at inverse temperature $\hat{\beta}_c$. The overlap between two solutions in this intermediate phase is

$$\frac{1}{2N} \left( \langle s^1 \cdot \sigma^1 \rangle \cdot \langle s^2 \cdot \sigma^2 \rangle \right) = \frac{1}{2N} \left| \langle s^1 \cdot s^2 \rangle + \langle \sigma^1 \cdot \sigma^2 \rangle \right| = \frac{1}{2N} \left| s^1 \cdot s^2 \right| > 0$$  \hspace{1cm} (84)

which is nonzero because there are only a few low-energy stationary points in system one, and there is a nonvanishing probability of selecting one of them twice. The distribution of this overlap is one-half the overlap distribution of a
frozen spin-glass at temperature $\beta$, a 1RSB system like the Random Energy Model. The value of $x$ corresponding to it depends on $\beta$, starting at $x = 1$ at $\beta_c$ and decreasing with increasing $\beta$. Globally, the joint complexity of the system is 1RSB, but note that the global overlap between different states is at most $1/2$. At $\beta > \beta_f$ there is a further transition.

This schematic example provides a metaphor for considering what happens in ordinary models when replica symmetry is broken. At some point certain degrees of freedom ‘freeze’ onto a subextensive number of possible states, while the remainder are effectively unconstrained. The overlap measures something in the competition between the number of these unconstrained subregions and their size.

### 9.2 $R$ and $D$: response functions

The matrix field $R$ is related to responses of the stationary points to perturbations of the tensors $J$. One adds to the Hamiltonian a random term $e_p \hat{H}_p = -\frac{1}{p} e_p \sum_{i_1 \cdots i_p} J_{i_1 \cdots i_p} s_{i_1} \cdots s_{i_p}$, where the $J$ are random Gaussian uncorrelated with the $J$s and having variance $\bar{F}^2 = p! / 2N^{p-1}$. The response to these is:

$$
\frac{1}{N} \frac{\partial \langle \hat{H}_p \rangle}{\partial x_a} = \lim_{n \to 0} \int \left( \sum_{i_1, \cdots, i_p} \hat{s}_i \right) \frac{\partial}{\partial J_{i_1 \cdots i_p}} \frac{1}{N} \frac{\partial \langle \hat{H}_p \rangle}{\partial x_a}
$$

Taking the average of this expression over disorder and averaging over the equivalent replicas in the integral gives, similar to before,

$$
\frac{1}{N} \frac{\partial \langle \hat{H}_p \rangle}{\partial x_a} = \lim_{n \to 0} \int D[C, R, D] \frac{1}{N} \sum_{a b} (\beta c_{a b} + pR_{a b} c_{a b}^{p-1}) e^{n \sum_{(C, R, D)}}
$$

$$
= \beta + p r_d - \int_0^1 dx c^{p-1}(x) (\beta c(x) + p r(x))
$$

The responses as defined by this average perturbation in the pure $p$-spin energy can be directly related to responses in the tensor polarization of the stationary points:

$$
\frac{1}{N^p} \sum_{i_1 \cdots i_p} \frac{\partial \langle \hat{s}_{i_1} \cdots \hat{s}_{i_p} \rangle}{\partial J_{i_1 \cdots i_p}^{(p)}} = \frac{1}{N} \frac{\partial \langle \hat{H}_p \rangle}{\partial x_a}
$$

In particular, when the energy is unconstrained ($\beta = 0$) and there is replica symmetry, the above formulas imply that

$$
\frac{1}{N} \sum_i \frac{\partial \langle \hat{s}_i \rangle}{\partial J_{i}^{(1)}} = r_d
$$

i.e., adding a linear field causes a response in the average stationary point location proportional to $r_d$. If positive, for instance, stationary points tend to align with a field. The energy constraint has a significant contribution due to the perturbation causing stationary points to move up or down in energy.

The matrix field $D$ is related to the response of the complexity to perturbations of the variance of the tensors $J$. This can be found by taking the expression for the complexity and inserting the dependence of $f$ on the coefficients $a_p$, then differentiating:

$$
\frac{\partial \Sigma}{\partial a_p} = \frac{1}{4} \lim_{n \to 0} \frac{1}{n} \sum_{a b} \left[ \beta^2 c_{a b}^p + p(2 \beta R_{a b} - D_{a b}) c_{a b}^{p-1} + p(p - 1) R_{a b}^2 c_{a b}^{p-2} \right]
$$

In particular, when the energy is unconstrained ($\beta = 0$) and there is no replica symmetry breaking,

$$
\frac{\partial \Sigma}{\partial a_1} = -\frac{1}{4} \lim_{n \to 0} \frac{1}{n} \sum_{a b} D_{a b} = -\frac{1}{4} d_d
$$

i.e., adding a random linear field decreases the complexity of solutions by an amount proportional to $d_d$ in the variance of the field.
When the saddle point of the Kac–Rice problem is supersymmetric,

\[
\frac{\partial \Sigma}{\partial a_p} = \beta \frac{1}{4 N^p} \sum_{i_1 \cdots i_p} \frac{\partial (s_{i_1} \cdots s_{i_p})}{\partial J^{(p)}_{i_1 \cdots i_p}} + \lim_{n \to 0} \frac{1}{n} \sum_{a,b}^{n} p(p - 1) R_{a,b}^2 C_{a,b}^{p-2}
\]

(91)

and in particular for \( p = 1 \)

\[
\frac{\partial \Sigma}{\partial a_1} = \beta \frac{1}{4 N} \sum_{i} \frac{\partial (s_i)}{\partial J^{(1)}_i}
\]

(92)

i.e., the change in complexity due to a linear field is directly related to the resulting magnetization of the stationary points for supersymmetric minima.

## 10 Conclusion

We have constructed a replica solution for the general problem of finding saddles of random mean-field landscapes, including systems with many steps of RSB. For systems with full RSB, we find that minima are exponentially subdominant with respect to saddles at all energy densities above the ground state. The solution should be subjected to standard checks, like the examination of its stability with respect to other RSB schemes. The solution contains valuable geometric information that has yet to be extracted in all detail, for example considering several copies of the system [56], or the extension to complex variables [57, 58].

A first and very important application of the method here is to perform the calculation for high dimensional spheres, where it would give us a clear understanding of what happens in realistic low-temperature jamming dynamics [59]. More simply, examining the landscape of a spherical model with a glass to glass transition from 1RSB to RS, like the 2 + 4 model when \( a_1 \) is larger than we have taken it in our example, might give insight into the cases of interest for Gardner physics [41, 42]. In any case, our analysis of typical 1RSB and FRSB landscapes indicates that the highest energy signature of RSB phases is in the overlap structure of the high-index saddle points. Though measuring the statistics of saddle points is difficult to imagine for experiments, this insight could find application in simulations of glass formers, where saddle-finding methods are possible.

A second application is to evaluate in more detail the landscape of these RSB systems. In particular, examining the complexity of stationary points with non-extensive indices (like rank-one saddles), the complexity of pairs of stationary points at fixed overlap, or the complexity of energy barriers [10, 60]. These other properties of the landscape might shed light on the relationship between landscape RSB and dynamical features, like the algorithmic energy \( E_{alg} \), or the asymptotic level reached by physical dynamics. For our 1RSB example, because \( E_{alg} \) is just below the energy where dominant saddles transition to a RSB complexity, we speculate that \( E_{alg} \) may be related to the statistics of minima connected to the saddles at this transition point.

## A Hierarchical matrix dictionary

Each row of a hierarchical matrix is the same up to permutation of their elements. The so-called \( k \)RSB ansatz has \( k + 2 \) different values in each row. If \( A \) is an \( n \times n \) hierarchical matrix, then \( n - x_1 \) of those entries are \( a_0 \), \( x_1 - x_2 \) of those entries are \( a_1 \), and so on until \( x_k - 1 \) entries of \( a_k \), and one entry of \( a_d \), corresponding to the diagonal.

Given such a matrix, there are standard ways of producing the sum and determinant that appear in the free energy. These formulas are, for an arbitrary \( k \)RSB matrix \( A \) with \( a_d \) on its diagonal (recall \( q_d = 1 \)),

\[
\lim_{n \to 0} \frac{1}{n} \sum_{a,b}^{n} A_{ab} = a_d - \sum_{i=0}^{k} (x_{i+1} - x_i) a_i
\]

(93)

\[
\lim_{n \to 0} \frac{1}{n} \ln \det A = \frac{a_0}{a_d - \sum_{i=0}^{k} (x_{i+1} - x_i) a_i} + \frac{1}{x_1} \log \left[ a_d - \sum_{i=0}^{k} (x_{i+1} - x_i) a_i \right]
\]

\[
- \sum_{j=1}^{k} (x_j^{-1} - x_{j+1}^{-1}) \log \left[ a_d - \sum_{i=j}^{k} (x_{i+1} - x_i) a_i - x_j a_j \right]
\]

(94)
where \( x_0 = 0 \) and \( x_{k+1} = 1 \). The sum of two hierarchical matrices results in the sum of each of their elements: \((a + b)_{ij} = a_{ij} + b_{ij}\) and \((a + b)_l = a_l + b_l\). The product \(AB\) of two hierarchical matrices \(A\) and \(B\) is given by

\[
(a \ast b)_{ij} = b_{ij}a_{ij} + a_{ij}b_{ij} + \sum_{j=0}^{i-1} (x_{j+1} - x_j) a_j b_j + \sum_{j=i+1}^{k} (x_{j+1} - x_j) (a_j b_j + a_j b_j)
\]

There is a canonical mapping between the parameterization of a hierarchical matrix described above and a functional parameterization that is particularly convenient in the twin limit \( n \to 0 \) and \( k \to \infty \) [61, 62]. The distribution of diagonal elements of a matrix \( A \) is parameterized by a continuous function \( a(x) \) on the interval \([0, 1]\), while its diagonal is still called \( a_d \). Define for any function \( g \) the average

\[
\langle g \rangle = \int_0^1 dx \, g(x)
\]

The sum of two hierarchical matrices so parameterized results in the sum of these functions. The product \(AB\) of hierarchical matrices \(A\) and \(B\) gives

\[
(a \ast b)_d = a_d b_d - \langle ab \rangle
\]

\[
(a \ast b)(x) = (b_d - \langle b \rangle) a(x) + (a_d - \langle a \rangle) b(x) - \int_0^x dy \, (a(x) - a(y))(b(x) - b(y))
\]

The sum over all elements of a hierarchical matrix \( A \) gives

\[
\lim_{n \to 0} \frac{1}{n} \sum_{ab} A_{ab} = a_d - \langle a \rangle
\]

The \( \ln \det = \text{Tr} \ln \) becomes

\[
\lim_{n \to 0} \frac{1}{n} \ln \det A = \ln(a_d - \langle a \rangle) + \frac{a(0)}{a_d - \langle a \rangle} - \int_0^1 dx \frac{\ln \left( \frac{a_d - \langle a \rangle - xa(x) + \int_0^x dy \, a(y)}{a_d - \langle a \rangle} \right)}{x^2}
\]
