1. Introduction

Cutting process analytical modelling allows us to understand the basic principles of the metal cutting phenomena while reducing the dependence on empirics by avoiding a large amount of time-consuming experiments. What is more important, it enables the evaluation of the main process factors such as force of cutting and aids in its prediction, which is required for the optimal execution of the machining operation. Many analytical models have been developed to date which can determine the relations between the variables involved in the cutting process. It is generally accepted that the cutting process in the course of metal machining is restricted to the area in front of the tool cutting edge due to intensive local shear deformation of the machined material [1 and 2].

Most of the current analytical models describe the cutting process as a simple two-dimensional model named orthogonal cutting. However, most cutting operations are actually three-dimensional and can be properly described using an oblique cutting model where the cutting edge is inclined at an angle of obliquity, $\lambda$, consistent with the primary motion course of the workpiece. Nevertheless, the simplified orthogonal model is generally used as a good demonstration of the oblique model. Figure 1 illustrates the orthogonal and oblique cutting models. In Fig. 1c, the workpiece, initially moving at speed $v$, goes through a plastic shearing strain and that leads to a chip streaming at $v_c$ after passing a certain shear area exemplified by the shear plane AB. Due to its importance as a measure of the energy efficiency of the cutting process, the shear plane orientation, $\phi$, is essential to analytical models for the development of the cutting process [3 and 4]. In addition to the stress at the cutting area, the orientation of the shear plane affects the kinematics of the machining process too. Merchant [5] designed the most simple and widely used model to determine the shear plane angle. He constituted a mathematical concept for describing force relationships in the cutting process.
Palmer and Oxley [9] experimentally studied the cutting process using a cinematography technique. Their results validated the multi-shear plane theory. They also concluded that tool-chip contact occurs some distance away from the tool tip, resulting in a kinematic dead zone at the tool tip. It was incorrectly assumed that no further plastic deformation occurs as the chip contacts the tool face and the secondary deformation observed is larger due to elastic chip flattening at this point. As proven conclusively from the later experimental work of Wallace and Boothroyd [6], the chip continues to undergo plastic deformation via shear upon contact with the tool rake face. A similar theory was included in Zorev’s [8] work on predicting the shear zone area.

Thus, two major deformation zones called the Primary Deformation Zone (PDZ) and Secondary Deformation Zone (SDZ) can be identified in the metal cutting process. Based on experimental observations, Roth and Oxley [10] developed a slip-line field model using velocity-dependent material flow lines that definitively identify the PDZ and SDZ. Based on the latter set of slip-line field models, the orthogonal cutting process can be presented as shown in Fig. 3. Depending on the subject matter under consideration, both single shear plane models and slip-line models have been used alternatively by researchers to study the cutting process [11].

Aside from the seminal work already mentioned, several excellent analytical models characterizing cutting mechanics are available. A list of analytical models is presented by Shaw [3] and will not be mentioned here for brevity.
2. Multifunction measuring system

The modelling system FEM is an important tool for rationalization of the metal cutting process, allowing industry to make parts faster, better, and at less cost but mainly ensuring the functional characteristics [12 and 13]. Innovative measurement methods of the process using thermal systems, high-speed scanning of dynamic processes and influence can be used to improve and verify the accuracy of these models. Four goals of manufacturing-related research at the Department of Machining and Manufacturing are: to develop and improve measurement techniques, to develop an understanding of the uncertainties involved with performing such measurements, to compare models of machining with thermal and visible spectrum images to verify the models, and to share this understanding with the machining community [14 and 15].

The formation of individual deformation zones is shown in Fig. 4, which shows a schematic of a typical image of an orthogonal cutting process. The relative motion between a cutting tool and a workpiece causes material to be removed from the workpiece. This removed material is referred to as a formation chip. Most of the deformation of the workpiece material occurs within a thin area called the shear zone [16 and 17].

Two of the many types of chips are called continuous and segmented. A continuous chip is a long ribbon of relatively uniformly deformed material. By contrast, a segmented chip has alternating zones of low and high shear strain. A zone of low strain in a segmented chip is called a segment. The zones of high strain between the segments are mechanically weak, so the long ribbons of material tend to break into short pieces [18]. These short pieces are more manageable than a continuous chip. Even when segmented chips do not break completely, there is generally a partial gap between the segments. The shear zone is somewhat stationary when continuous chips are formed, but often travels along with the chips when the chips are segmented. We will call the area surrounding the shear zone the face of the chip. The shear zone has a higher temperature than the face. For segmented chips, the shear zone generally also has a higher emissivity than the face [19 and 20].

The system used for measuring and observation processes in the cutting zone consists of a high-speed imaging camcorder, thermo-vision system and dynamometer for measurement of the cutting forces. Besides these sub-devices, there is a laboratory cold light for lighting the studied area and a computer for synchronizing all the measured data. This multi-axis measuring system (Fig. 4) was designed for the universal lathe SUI-40, but the construction of the stand guarantees some universality of the measuring system for other types of machines.

Dynamical monitoring of the cutting process can be provided by the high-speed imaging camcorder, which ensures high-speed imaging in all experiments, with an imaging frequency of 1000fps. For detailed study, a super-macro lens Raynox MSN-202 with 20x magnification was used. Based on this optical system, we can capture an area of 4mm x 3mm.

The actual heat distribution can be monitored by the thermo-vision system which captures the thermal field in the cutting zone and heat distribution when machining. This compact camera allows us to measure temperatures up to 1200°C with a tolerance of ±2°C. Special optics with deflected lens allows us to place the camera outside of the perpendicular on the scanned object [14].

The piezoelectric 3-component dynamometer can capture fast dynamic force relations measured as cutting forces with high-speed scanning up to 1x10^5Hz. All the applied measuring devices are integrated on a macro-stand (Fig. 5). For correct mounting and manipulation, the macro-stand was designed with mounting on the lathe support in order to ensure the simultaneous motion of the camera and cutting tool.

Fig. 5 Macro-stand with triaxial feed for mounting of high-speed imaging camcorder which provides simultaneous movement of the cutting tool and camcorder
Nickel alloys are popular materials due to their high heat and creep resistance. Due to their specific properties, they are used in the aerospace industry. Due to their mechanical and chemical properties, they are included among the hard-machined materials. Because this material is characterized as having a combination of strength, toughness and hardness, it is necessary to choose specific cutting conditions [21 and 22]. These were chosen from the real cutting conditions used in practice and they are shown in the caption of Fig. 6. All experiments were performed without coolant because this would prevent the scanning by the high-speed thermo-graphic camera [23 and 24].

To prevent the influence of bound-cutting by the cutting edge effect, the technology of free-cut turning was chosen. The free cutting approach ensures as much as possible of the area of the cutting zone and also ensures that the chips depart in the opposite direction of action from that of the cutting tool [25 and 26].

3. Evaluation of the experiments

Measurements of cutting forces were conducted in various cutting conditions. As can see, the cutting force $F_f$ increased with the increasing feed and, conversely, cutting force $F_c$ decreased with increasing cutting speed (Fig. 6). It can be deduced from the measured data that the behaviour of nickel alloy Monel 400 is similar to the machining austenite of steel, but with a higher ratio of cutting forces considering the mechanical properties of this alloy.

From the monitoring of the dynamic course of the cutting forces, we can say that the cutting process is created by frequent accumulation of material as the built-up edge. The built-up edge has considerable influence on the cutting geometry, which causes the high dynamization of the cutting process.

Methods of examining and monitoring the cutting zone are developing with available technologies that are applicable for the monitoring and capturing of processes during the cutting
images show the formation of deformation processes, and are thus a suitable basis for new simulation and mathematical models.

The data obtained from the individual processes during the experiments have a direct relationship with each other because they were obtained simultaneously in a single machining process. In this case they provide especially a waveform record of the cutting forces, the time course of development of the temperature field, and visual records of the deformation phenomena during the machining process. The measured data were then processed on a computer into video clips that show how individual phenomena are associated with each other in the cutting zone (Fig. 10).

Sequential frames from multi-parametric output are shown schematically: In the upper left corner is a visual record from the high-speed camera. In the top right corner is a thermo-graph or the thermo-graphic time course of the thermo-vision system (this is slowed down for the high-speed camera frame rate). Below the video output is the waveform of the components of the cutting force on the left and the graphic time course of the development of the average temperature in the cutting zone.

During the turning of the nickel alloy Monel 400, the phenomenon occurs that the primary contact of the tool and machined material is highly loaded with the pressure of transition from forming to the cutting process. In the first frame (Fig. 11), it is possible to see the formation of elementary chips after process [27]. The most common possibilities include research of deformation processes based on finished changes after the end of the cutting process, such as examining metallographic samples from the cutting zone, acquired by the immediate interruption of the cutting process, etc. [28 and 29]. This research reached sufficient and complete conclusions about the processes in the cutting zone, but in a static concept after the finished process. Therefore, it was necessary to find new innovative technologies for idealized physico-mathematical models as the previous experimental outcomes provide information about finished processes only [30 and 31]. It is necessary to record deformation processes in the form of a high-speed video and image sequences from which the creation, shape of chips and deformations in the cutting zone when machining can be evaluated, and these can be made from monitoring the cutting zone by a high-speed imaging camcorder [32 and 33].

In the high-speed video records, it is possible to see the formation of deformation processes depending on the cutting conditions. At low cutting speeds, the formation of elementary chips occurs, giving rise to high dynamic shocks which load and cyclically fatigue the cutting edge up to destruction (Fig. 7).

At the higher cutting speeds, the formation of continuous ribbon chip occurs, which has a different character of influence on the cutting edge where thermal effects outweigh the dynamic shocks and cyclic loadings (Fig. 8).

In the last picture (of Fig. 8) of the measuring system, the primary and tertiary area and their influence on the machined surface can be seen. This surface has the effect of pooling the high stress loadings which act negatively on the functional properties of parts.

By application of the notch, there was simulation of discontinuous cut in which the monitoring of the cutting process before and after tensioning of the technological system was important. Cutting conditions were identical to the conditions of the continuous cut. In this experiment, there is formation of the same chip which has an identical character to that in the previous experiment. The cutting edge of the cutting tool is exposed to temperature mainly and dynamic shock and cyclic loadings (Fig. 9).

In each picture of the measuring system, relaxation of the technological system (tool – workpiece) can be seen with the transition to the tensioning of the technological system. These
4. Conclusions

The multifunction measuring system designed for the monitoring of processes in the cutting zone allows observation of the deformations, temperature field, forming and shape of chip directly in the course of the cutting process, without interruption. We can evaluate the measured data in the specific dependences which exist between them.

The forces which act in the process change depending on the cutting conditions, structure and mechanical properties of the machined material.

The deformation processes which are in the cutting zone during machining take place at high speed. Under normal observation with the naked eye or by microscope only, these processes are not identifiable. Detailed observation is possible using the high-speed imaging camcorder. In this way, we can

The microstructure and mechanical properties of the materials caused a built-up edge to form almost throughout the cutting process. The components of cutting force during the formation of the built-up edge and its subsequent “holding on” to the front face of the cutting tool grew very high. After being picked, the cutting forces decreased sharply. With the new creation of a built-up edge, the whole process was repeated. This iterative cycle resulted in a specific shape of waveform of the components of the cutting force. In the third frame of Fig. 11 the built-up edge and increased components of the cutting force can be seen. The last frame of Fig. 11 captures the moment immediately after the built-up edge is picked.

The cutting conditions: continuous cutting; \( v_c = 70 \text{ m min}^{-1} \); \( f = 0.21 \text{ mm} \); \( a_p = 6 \text{ mm} \); machine: univ. lathe SUI-40; cutting tool: holder STFCL 2525M, insert TCMW 16-160700

Fig. 11 Selected frames from video output of the multifunction measuring system

the intrusion of the cutting tool into the action, and after the stabilization of the cutting process, flat spiral chips were created.
observe not only the deformation processes but also the creation and formation of chips.

With the multifunction measuring system, we can better intensify the machining process, cutting conditions and so improve the product quality. We can also reduce the cost, because this system allows simultaneous measuring. Based on the observations of the deformation processes in the cutting zone, as well as the creation and formation of chips, we can also optimize the shape of the cutting inserts.
