In Brief

To evaluate the effect of the nucleolus in plant genome organization, Pontvianne et al. identify nucleolus-associated chromatin domains (NADs) in A. thaliana leaves. NADs are enriched in regions displaying heterochromatic signatures. We find roles for Nucleolin 1 (NUC1) and the nucleolus in the spatial organization of chromosomes and also in telomere maintenance.

SUMMARY

The nucleolus is the site of rRNA gene transcription, rRNA processing, and ribosome biogenesis. However, the nucleolus also plays additional roles in the cell. We isolated nucleoli using fluorescence-activated cell sorting (FACS) and identified nucleolus-associated chromatin domains (NADs) by deep sequencing, comparing wild-type plants and null mutants for the nucleolar protein NUCLEOLIN 1 (NUC1). NADs are primarily genomic regions with heterochromatic signatures and include transposable elements (TEs), sub-telomeric regions, and mostly inactive protein-coding genes. However, NADs also include active rRNA genes and the entire short arm of chromosome 4 adjacent to them. In nuc1 null mutants, which alter rRNA gene expression and overall nucleolar structure, NADs are altered, telomere association with the nucleolus is decreased, and telomeres become shorter. Collectively, our studies reveal roles for NUC1 and the nucleolus in the spatial organization of chromosomes as well as telomere maintenance.

INTRODUCTION

An important aspect of transcriptional regulation is the modification of gene accessibility to transcription factors and RNA polymerases. Gene accessibility depends on local chromatin structure but also on the nuclear context and subnuclear localization of a gene. In recent years, local chromatin structure and its effect on gene expression has been extensively studied, with genome-wide approaches defining the chromatin contexts for each gene (Filion et al., 2010; Kharchenko et al., 2011; Roudier et al., 2011; Roy et al., 2010; Wang et al., 2008) and identifying chromatin states that correlate with gene activity (Bickmore and van Steensel, 2013; Sequeira-Mendes and Gutierrez, 2015). However, nuclear context is also important in that the position of a gene with respect to nuclear pores, the nuclear lamina, or the nucleolus as well as its inter- or intrachromosome interactions with other loci can affect its transcriptional regulation (Bickmore and van Steensel, 2013).

In mammalian cells, large portions of the genome associate with the nuclear lamina at the periphery of the nucleus and are identified as lamina-associated domains (LADs). LADs are essentially composed of regions with silent chromatin signatures and can represent up to 35% of the nuclear genome (Guelen et al., 2008). Chromosome regions can also associate with the nucleolus, the largest nuclear body. The nucleolus forms as a direct consequence of ribosome biogenesis, but it is also implicated in stress sensing, cell-cycle progression, viral replication, and ribonucleoprotein (RNP) biogenesis (Boisvert et al., 2007; Boulon et al., 2010; Pederson, 2011). Nucleolus-associated chromatin domains (NADs) represent several megabases of the human genome from all 23 chromosomes, typically regions displaying silent chromatin signatures (Németh et al., 2010; van Koningsbruggen et al., 2010). Comparison of NADs and LADs has revealed substantial overlap. Interestingly, LADs that do not relocate to the nuclear periphery after mitosis often associate instead with the nucleolus (Kind et al., 2013, 2015). An important aspect of the nucleolus is that it creates a large domain within the nucleus from which RNA polymerase II (RNA Pol II) is absent (Schubert and Weisshart, 2015). There is no membrane or physical barrier separating the nucleolus from the nucleoplasm, suggesting that nucleolar chromatin bears modifications that are refractory to Pol II transcription. Indeed, mutations in chromatin modifiers that localize and act (in part) in the nucleolus, such as Arabidopsis HISTONE DEACETYLASE 6, result in Pol II detection in the nucleolus as well as Pol II association with rRNA genes, which are usually transcribed only by Pol I (Early et al., 2010). In plant cells, neither LADs nor NADs have been identified so far. Importantly, plants lack genes orthologous to those encoding nuclear lamins in other eukaryotes. However,
little nuclei (LINC) (also called CRWN) proteins share some characteristics with lamins, including coiled-coil domains (Dittmer et al., 2007). However, an association between this complex and chromatin has not yet been demonstrated.

The relationship between rRNA gene transcription and organization and the nucleolus has been studied extensively (Benoit et al., 2013; Grummt and Längst, 2013; McStay and Grummt, 2008; Tucker et al., 2010). In each cell, active and inactive rRNA genes coexist, and their ratio varies depending on the needs of the cell. Most silent copies of rRNA genes are excluded from the nucleolus, where RNA polymerase I is located, but they relocate into the nucleolus in mutants that disrupt silencing (Pontvianne et al., 2013).

rRNA genes are arranged in tandem arrays (known as nucleolus organizer regions [NORs]) that span millions of base pairs. Because silenced rRNA genes comprise a NOR on a different chromosome from active rRNA genes in Arabidopsis thaliana (ecotype Col-0), changes in rRNA gene activity that are accompanied by changes in their subnuclear localization (Pontvianne et al., 2013) are predicted to affect chromosome organization within the nucleus, at least locally. Using a technique that allows us to isolate nucleoli from plant tissue using fluorescence-activated nucleolar sorting (FANoS) combined with deep sequencing, we now report the identification of genomic NADs in the cell nuclei of A. thaliana leaves. We show that NADs other than rRNA genes are mainly composed of transposable elements (TEs) but that NADs also contain genes that are weakly expressed or unexpressed. Analyses of NADs in the nucleolin 1 (nuc1) mutant, which disrupts rRNA gene silencing at the inactive NOR and alters nucleolar structure, reveals that NAD composition changes in nuc1 versus wild-type nuclei. Interestingly, nuc1 mutants also display shortened telomeres, and telomerase activity is detected in immunoprecipitated NUC1 fractions, revealing an effect linking the nucleolar protein NUC1 with telomere maintenance.

RESULTS

Identification of NADs in A. thaliana
DNA staining using the fluorescent dye DAPI allows the visualization of nuclear DNA and its distribution within the nucleus. In nuclei of 3-week-old A. thaliana leaves, bright DAPI-intensive signals correspond to chromocenters that include the highly compacted peri-centromeric heterochromatin of the ten chromosomes. On the other hand, euchromatin is less compacted peri-centromeric heterochromatin of the ten chromosomes. On the other hand, euchromatin is less compact, and therefore the DAPI signal is less intense. DAPI staining of nuclei also allows one to identify the nucleolus, which appears as a black cavity in the nucleus because of a 3-fold lower concentration of DNA in the nucleolus compared with the surrounding nucleoplasm (excluding centromeres) (Figure 1A; see fluorescence intensity plot). To characterize this nucleolar DNA, we took advantage of a method that we recently developed for the purification of nucleoli by a modified FACS approach. In this protocol, a nucleolar protein, Fibrillarin, is fused to yellow fluorescent protein (FIB2:YFP) and stably expressed in wild-type Col-0 plants to specifically mark nucleoli (Figure 1A; Pontvianne et al., 2013). Nucleoli liberated from sonicated nuclei are then isolated by fluorescence-activated nucleolar sorting (FANoS). Purified, sorted nucleoli stained by DAPI allow detection of nucleolar DNA (Figure 1B). As in the nucleoplasm, nucleolar DNA is not homogeneously distributed in the nucleolus, and thus stronger DAPI-stained signals are visible in some regions. Because the nucleolus forms around actively transcribed rRNA genes, rRNA genes are detected in nucleolar DNA, as expected, using DNA fluorescence in situ hybridization (FISH) and a probe flanking the transcription initiation site of rRNA genes (Figure 1B; see 45S rDNA signals). Interestingly, rDNA FISH signals do not completely overlap with DAPI-stained nucleolar DNA, suggesting that nucleolar DNA does not consist solely of rRNA genes.

To determine the sequence of nucleolar DNA, two samples consisting of 10^6 nucleoli and two samples of 5 x 10^5 nuclei from 3-week-old plant leaves were isolated. The nuclear or nucleolar DNA was then purified and sequenced, and reads were mapped to the Arabidopsis TAIR10 reference genome. To identify genomic regions present in the nucleolus, we compared read densities of nuclear or nucleolar DNA for each of the two replicates. The nuclear fraction served as an input control to evaluate the relative enrichment of genomic regions in the nucleolar DNA. Genomic regions with a nucleolar versus nuclear (No/N) fold enrichment ratio greater than 2 in both replicates were considered NADs (Figure 1C). Excluding rRNA genes, NADs represent 4.2% of the genome (~5.7 Mb). Around 30% of NADs correspond to genes, 35% correspond to TEs, and the rest correspond to intergenic regions (Figure 1D).

The No/N fold enrichment ratio was plotted along each of the five chromosomes in 100-kb windows to scan for genomic regions associated with the nucleolus (Figure 1E). In A. thaliana, 45S rRNA genes are arranged in tandem repeat arrays in NORs located on the left arm of chromosomes 2 and 4 (Figure 1E, NOR2 and NOR4). In A. thaliana leaves, only NOR4 associates with the nucleolus and is actively transcribed, whereas NOR2 is inactive and is excluded from the nucleolus (Chandrasekhar et al., 2016; Fransz et al., 2002; Pontvianne et al., 2013). This genomic configuration and selective expression of 45S rRNA genes is reflected in the enrichment of NADs along the left arm of chromosome 4 and their near absence from the left arm of chromosome 2 (Figure 1E). In fact, the entire left arm of chromosome 4 (or Chr4S for “chromosome 4 short arm”), including its pericentromeric and centromeric regions, associates with the nucleolus (Figure 1E). In contrast, the left arm of chromosome 2 behaves like chromosomes 1, 3, and 5, which do not harbor NORs. Subtelomeric regions from all five chromosome pairs are also enriched in the nucleolus, consistent with previous work demonstrating telomere clustering at the periphery of the nucleolus (Armstrong et al., 2001).

NADs Are Enriched in Inactive Chromatin Marks and TEs
We took advantage of published epigenomic data to characterize the types of chromatin that associate with NADs. Among the nine chromatin states defined based on their histone marks and histone variant content (Sequeira-Mendes et al., 2014), and presented in Figure S1A, we found that four were statistically
enriched in NADs (Figure 2A). This includes chromatin states 8 and 9, which show an enrichment for CG methylation, and for the silent chromatin marks histone H3 lysine 9 dimethylation and histone H3 lysine 27 monomethylation (H3K9me2 and H3K27me1, respectively) (Sequeira-Mendes et al., 2014). Chromatin states 8 and 9 are typically associated with TEs and intergenic regions. In addition, chromatin states 4 and 5, which are characterized by high levels of H3 lysine 27 trimethylation (H3K27me3), are also enriched in NADs. Although almost no genes (other than TEs) are present in chromatin states 8 and 9, some are present in chromatin states 4 and 5. We therefore analyzed the relative expression of polyA+ RNA from NAD genes in these different chromatin states to establish a possible correlation between NADs and gene expression (Durut et al., 2014). All four of the chromatin states that are enriched in NADs (4, 5, 8, and 9) correspond to genomic regions depleted in actively transcribed genes (Figures 2B and S1B; Sequeira-Mendes et al., 2014).

Because NADs are enriched in TEs, we examined the relative contribution of each TE superfamily to NADs. 3,640 TEs were identified with a No/N fold enrichment ratio greater than 2 (NAD-TEs, Data S1). In general, no TE superfamily is particularly enriched (Figure 2C). DNA/Mariner, DNA/Pogo, DNA/Tc1, and pseudo-LINE elements are slightly overrepresented, whereas LTR/Copia or SINE superfamilies are underrepresented. The biased presence of particular TE superfamilies in NADs is probably a consequence of their relative abundance in peri-centromeric or knob regions (Figure 2D).

**Description of the Genes Present in NADs**

Although a large portion of NAD loci correspond to TEs, there are also many genes. Using the Araport11 annotation database and excluding 317 Araport11-referenced TEs and rRNA genes, a total of 907 genes were identified as NAD genes, which represent around 3% of all genes (Data S2). The relative position of NAD genes along all five chromosomes follows the general distribution of NADs, being enriched in subtelomeric regions and in the short arm of chromosome 4 (Figure 3A). NAD gene distribution among eukaryotic orthologous groups of proteins (KOG) revealed that most types of KOGs are represented among NAD genes, with only a slight enrichment for the “cell mobility” category. However, only 21 genes belong to this particular category,
and the 4.7% proportion observed here is only due to the association of one gene and is therefore not considered significant. Genes implicated in “translation, ribosomal structure, and biogenesis,” and which are thus linked to nucleolar function, are not enriched among NAD genes either. However, two other categories of genes are particularly enriched: pseudogenes and tRNA genes (Figure 3B). Among the 915 pseudogenes referenced in the *A. thaliana* genome, 72 (7.9%) are present in NAD genes. Moreover, 7.2% of tRNA genes belong to NADs. Interestingly, almost all tRNA isoacceptor types are present in NADs, with the exception of tRNA-His, which is the smallest tRNA gene family in *A. thaliana* (Figure 3D). The global distribution of pre-tRNA genes among the ten chromosome arms shows that 31% are clustered on the short arm of chromosome 2 (Figure S2).

Because RNA pol II is not observed in the nucleolus, we expected that predicted pol II-transcribed genes that are among NAD genes would likely be unexpressed or expressed at low levels. Global nuclear gene and NAD gene expression analyses did indeed reveal a bias in expression that supports this hypothesis (Figure 3C).

**Effect of NOR Positioning and Nucleolus Structure on NAD Composition**

In wild-type *A. thaliana* leaves, only NOR4 interacts with the nucleolus, whereas NOR2, composed of inactive rRNA genes, is excluded from the nucleolar periphery. In null mutants for the NUCLEolin 1 gene (*nuc1*), NOR2 and NOR4 both associate with the nucleolus, and the NOR2 rRNA genes that are normally silenced during development in wild-type leaves fail to silence (Earley et al., 2010; Pontvianne et al., 2010). VAR1 designates a class of rRNA genes that represent 50% of the entire set of rRNA genes. Because VAR1 rRNA genes are present at the inactive NOR2, they are excluded from the nucleolus, which explains the lack of VAR1 gene expression in wild-type Col-0 (Chandrasekhar et al., 2016; Pontvianne et al., 2010). However, we previously demonstrated that VAR1 rRNA genes are expressed in *nuc1* mutants (Pontvianne et al., 2010). Here we show that VAR1 rRNA genes indeed associate with the nucleolus in the *nuc1* mutant by using PCR analyses of FACS-isolated nuclear or nucleolar DNA (Figure 4A). To test the effect of NOR2 association with the nucleolus on NAD composition, we isolated and sequenced the DNA from FACS-isolated nuclei or nucleoli of *nuc1*. In wild-type Col-0, chromosome 4 harbors the largest proportion of NADs because of the association of Chr4S with the nucleolus, followed by chromosome 2 (Figure 1). However, in *nuc1*, the short arms of both chromosomes 2 and 4 (Chr2S and Chr4S) associate with the nucleolus (Figure 4B). This observation correlates with the transcriptionally active state of both NOR2 and NOR4 in *nuc1* (Figure 4A).

The pericentromeric and centromeric regions of chromosomes 1, 3, and 5 become enriched in *nuc1* mutant NADs (Figures 4C and S3). However, Modullo, the *Drosophila melanogaster* homolog of nucleolin, is required for centromere sequestration at the periphery of the nucleolus (Paddeken et al., 2013) so that centromere association with *Arabidopsis* nucleoli might be expected to decrease rather than increase in *nuc1*.
mutants. Because centromeric chromocenters are easily detected by DAPI staining, we assessed their relative positions with respect to the nucleolus in wild-type Col-0 and in nuc1 mutant nuclei from 3-week-old leaves (Figure 4D). In addition, immunolocalization using an antibody recognizing the centromeric Histone 3 (cenH3) were used to validate centromere distribution. Consistent with the NAD analyses, centromeres associate more strongly with the nucleolus in nuc1 relative to wild-type (p < 2.2e-16) (Figure 4D). In 16% of the nuclei, a strong DAPI-stained signal can be detected inside Col-0 nucleoli; by contrast, more than 72% of nuc1 nucleoli harbor these heterochromatin signatures (p < 2.2e-16) (Figure 4D). The altered centromere positioning in nuc1 mutant nuclei suggests, as in D. melanogaster, a role for NUC1 in heterochromatin distribution but in an opposing way.

**NAD Gene Depletion in the nuc1 Mutant**

822 NAD TEs (Data S3) and 117 NAD genes (Data S4) can be identified in nuc1 with a No/N fold enrichment ratio greater than 2. Their distribution along the five chromosomes (Figure 5A) is quite different from that seen in wild-type Col-0 (Figure 3A). Although 65% of Col-0 NAD genes were distributed on chromosome 4, only 20% of nuc1 NAD genes are present on this chromosome. By contrast, 13% of Col-0 NAD genes were found on chromosome 2, but this proportion increased to 46% in the nuc1 mutant. Nonetheless, the NAD gene pool between wild-type Col-0 and nuc1 overlaps significantly because 80% of nuc1 NAD genes are also NAD genes in Col-0 (Figure 5B). To further characterize NAD genes that strongly associate with the nucleolus, we identified NAD genes in either wild-type Col-0 or nuc1 that have an No/N fold enrichment ratio greater than 3.
Figure 4. Identification of NADs in the nuc1 Mutant

A) PCR detection of rRNA gene variant types in DNA of purified nuclei (N) or nucleoli (No) of wild-type (Col-0) or nuc1 plants.

B) Chromosome plots displaying the relative enrichment of the genomic sequence as 100-kb windows in the nucleolus on each five chromosomes in the nuc1 mutant.

C) DAPI-stained nuclei from WT Col-0 (left) or from nuc1 plants (right). The green signal represents the fluorescence obtained from the anti-centH3 antibody. Scale bars, 5 μm.

D) Box plot showing the relative proportion of nucleolus-associated centromeres (CEN) in WT Col-0 or the nuc1 mutant. The analysis was performed on 100 nuclei/sample.

(Figure 5C). In both cases, about 100 NAD genes were identified, and 51 were shared in both genotypes. Among these common loci are tRNA genes (8) and pseudogenes (21), demonstrating their strong, reproducible association with the nucleolus, even in the nuc1 mutant context, where nucleolar structure is disrupted (Pontvianne et al., 2007).

Because RNA pol II is generally not detected in the nucleolus, we hypothesized that the physical association of NAD genes with the nucleolus may reflect their transcriptional status. We thus took advantage of the fact that several hundred NAD genes detected in the wild-type no longer associate with the nucleolus in the nuc1 mutant to see whether loss of nucleolar localization correlates with their activity. RNA deep sequencing analyses of Col-0 versus the nuc1 mutant from 3-week-old leaves were performed in triplicate, allowing us to identify 100 upregulated genes in the nuc1 mutant (Figure 5C). Among these 100
upregulated genes, four are NAD genes in the wild-type but not in the nuc1 mutant. Three of these four genes, which are all on chromosome 4, are shown in Figures 5D–5F; they encode for a P loop nucleoside triphosphate hydrolase (AT4G05380), a WRKY transcription factor (AT4G01720), and a pseudogene (AT4G08093), respectively. Note that only genes considered up-regulated in nuc1 by the software Cuffdiff were taken into consideration here. However, more transcripts can be detected in the same region of Chr4S, where nucleolar association in nuc1 is weaker than in the wild-type (Figure S4). These observations reinforce a possible link between gene activity and nucleolus association.

**Nucleolar Clustering of Telomeres Is Disrupted in the nuc1 Mutant**

In nuc1 mutants, nucleolar organization is disrupted (Pontvianne et al., 2007). Because previous studies have shown that Arabidopsis telomeres cluster at the periphery of the nucleolus (Armstrong et al., 2001; Fransz et al., 2002), nucleolar disruption in nuc1 might alter telomere positioning, potentially influencing the association of linked chromosomal loci with the nucleolus. In the global distribution of NADs along all five chromosomes (Figure 1E), a convex pattern is observed, meaning that sub-telomeric regions are largely enriched in the nucleolus. Interestingly, the sub-telomeric nucleolar association is lower in the...
nuc1 mutant compared with wild-type Col-0, especially for chromosomes 1, 3, and 5 (Figure 4B). This observation is confirmed by analysis of the relative enrichment in the nucleolus of genomic regions in the nuc1 mutant compared with wild-type Col-0 (Figure 6A). The latter distribution pattern is concave, demonstrating the enrichment of the centromeric and pericentromeric regions as NADs, but also the depletion of sub-telomeric regions, in the nuc1 mutant.

The deep sequencing data strongly suggest that nucleolar clustering of telomeres is affected in the nuc1 mutant. To test this hypothesis with a different method, we conducted DNA FISH analyses of the telomere distribution in wild-type Col-0 and nuc1 leaf nuclei by using telomere-specific probes (Figures 6B–6D; Figure S5). As expected, FISH signals tend to associate with the nucleolus in wild-type Col-0 (Figure 6B). However, a significant decrease in telomere association with the nucleolus is observed in the nuc1 mutant (Figure 6C), with quantification revealing an 83% telomere-nucleolus association in wild-type Col-0 versus 53% in the nuc1 mutant (Figure 6D). Importantly, telomeres that do not associate with the nucleolus in nuc1 do not appear to be clustered in an alternative nucleoplasmic subcompartment.

Mutations in NUC1 Cause Telomere Shortening on All Chromosome Arms

The biological function of telomere nucleolar clustering remains unknown, but we reasoned that it could have an effect on telomere maintenance. The analysis of terminal chromosome restriction fragments (TRFs) allows one to determine global telomere size. We used this technique to determine telomere size distributions in wild-type Col-0 and nuc1 mutants. In addition, telomere size was analyzed in mutants for genes encoding FASCIATA1 (fas1-4) and FASCIATA2 (fas2-4), which mediate replication-dependent histone deposition and whose disruption strongly reduces telomere size (Mozgova et al., 2010). Compared with wild-type Col-0, a significant TRF length reduction was observed in both nuc1 mutant alleles, comparable with that observed in fas1 and fas2 mutants (Figure 7A). However, no difference is observed between wild-type Col-0, the nuc2 mutant, or the complemented nuc2 mutant, demonstrating the specific effect of the nuc1 mutations.

We previously demonstrated the importance of NUC1 on rRNA gene regulation, which occurs in NOR2 and NOR4 (Pontvianne et al., 2010, 2007). In A. thaliana, the terminal rRNA genes from NOR2 and NOR4 are directly capped by telomere repeats (Copenhaver and Pikaard, 1996). To determine whether telomeres of NOR-bearing chromosomes are differentially affected, we used a PCR-based method called primer extension telomere repeat amplification (PETRA) (Heacock et al., 2004) on multiple chromosome arms (Figures 7B–7E). In agreement with the data from TRF, telomeres on all studied chromosome arms display an ~30% loss of length in the nuc1 mutants compared with wild-type Col-0, which is equivalent to the loss observed in fas1 and fas2 mutants. Together, these observations demonstrate that telomeres from all chromosome arms are shortened...
in nuc1 and thus are not dependent on the presence of rRNA genes near the affected telomere.

The fact that telomerases tend to associate less frequently with the nucleolus and are shorter in nuc1 mutants compared with the wild-type indicates that NUC1 is somehow important for telomere biology. It remains unknown if these effects are due to NUC1 disruption, nucleolus disorganization, or both. To test whether NUC1 interacts directly or indirectly with the telomerase, a telomere repeat amplification protocol (TRAP) was performed using immunoprecipitated NUC1 (Figure 7F). Immunoprecipitation (IP) was performed using an anti-FLAG antibody and protein extracts of WT Col-0 or nuc1 mutant complemented with a transgene encoding NUC1 fused to a FLAG epitope tag under the control of its own promoter (NUC1-FLAG) (Pontvianne et al., 2010). Telomerase activity is markedly stronger in the NUC1-FLAG coIP sample (Figure 7F, left, FLAG-IP) compared with the background signal observed in the Col-0 plant. These data suggest that NUC1 interacts with and coIPs telomerase activity, suggesting a role of NUC1 in telomere biology.

**DISCUSSION**

**The Effect of NOR-Nucleolus Associations on Nuclear Architecture**

In mammalian cells, the nuclear distribution of DNA is governed by individual chromosome territories (Gibcus and Dekker, 2013). Although chromosome territories can be seen in Arabidopsis (Gibcus and Dekker, 2013). Architecture

**Pol II-Transcribed Genes Are Present in NADs**

Our data have allowed the comprehensive identification of genetic loci that associate with the nucleolus (NADs), including many genes (NAD genes). The majority of NADs correspond to repeat elements such as TEs that are transcriptionally silenced by repressive histone modifications and DNA methylation (Ito and Kakutani, 2014). Whether the association of these loci with the nucleolus participates in transcriptional repression is an open question. However, because only a fraction of TEs associate with the nucleolus, being in a NAD is certainly not a prerequisite for silencing. Our data also demonstrate the presence of genes other than TEs in NADs. In the human nucleolus-associated genome, genes encoding for olfactory receptors or transcription factors were found to be enriched in NAD genes (Németh et al., 2010; van Koningsbruggen et al., 2010). In our data, the most enriched non-rRNA gene loci are pseudogenes. Because they potentially encode truncated or non-functional proteins, keeping them silent is perhaps the best way to prevent a potential deleterious effect of their expression. Importantly, pseudogenes remain highly enriched in the nucleolus of nuc1 mutant cells, although nucleolar structure is greatly disrupted (Figure 5).

Genes encoding pre-rRNAs are also significantly enriched in the nucleolus. Although this association has never been described in plant cells, previous reports showed a nucleolar association of rRNA genes in yeast and human cells (Németh et al., 2010; Thompson et al., 2003). Interestingly, the presence of a nearby rRNA gene was shown to antagonize pol II RNA transcription in yeast because of its clustering near or in the nucleolus (Wang et al., 2005). This phenomenon is known as rRNA-mediated silencing and involves the proteins MOD5 and Condensin (Haeseler et al., 2008; Pratt-Hyatt et al., 2013). However, we show here that several hundred functional genes associate with NADs, and only a small portion have a rRNA gene nearby. Other mechanisms to explain rRNA gene nucleolar association may exist. Whether their association with the nucleolus is biologically relevant remains unknown, but because RNA pol II is depleted in the nucleolus, sequestration of genes to NADs likely reflects a chromatin status or location not conducive to pol II transcription. This hypothesis is reinforced by the observation that NAD genes are typically silent or expressed at low levels but also by the fact that some genes that were NAD genes in Col-0, but not in nuc1, became significantly upregulated in nuc1 (Figure 5). These observations reinforce a possible link between gene silencing and nucleolus association.

Regulation by nucleolar sequestration is known to control certain protein functions, especially during stress conditions. In mammalian cells, rDNA intergenic transcripts accumulate in the nucleolus after heat shock and provoke the nucleolar sequestration of nuclear proteins like the DNA methyltransferase DNMT1, the proteasome factor SUG1, or POLD1, a key factor of DNA replication (Audas et al., 2012a, 2012b). A similar mechanism may exist to regulate transcription by a phenomenon that could be named transcriptional regulation by nucleolar sequestration.

1582 Cell Reports 16, 1574–1587, August 9, 2016
Figure 7. NUC1 Interacts with Telomerase, and Its Disruption Induces Telomere Shortening

(A) TRF analyses of telomere length in two WT Col-0 replicates, two nuc1 mutant alleles, the nuc2-2 or complemented nuc2 mutant, as well as in the fas1-4 and fas2-4 mutant.

(B–E) PETRA analyses of telomere length in two nuc1 mutant alleles, two replicates of WT Col-0, as well as in fas1-4 and fas2-4 mutants. Chromosome-specific probes were used to detect the telomere of the left arm of chromosome 3 (B), the right arm of chromosome 4 (C), as well as the left (D) or right (E) arm of chromosome 5.

(F) Telomerase activity was analyzed in fractions obtained during the IP-TRAP experiment using pNUC1-NUC1-FLAG-tagged and WT Col-0 plants. Total input, total protein extract prior to IP; unbound, unbound fraction after the capture by ANTI-FLAG magnetic beads; 1st wash, first wash of the fraction bound to magnetic beads with buffer W; 2nd wash, second wash of the fraction bound to magnetic beads with buffer W; FLAG-IP, a fraction specifically bound to magnetic beads; denatured, reaction with denatured total protein extract (5 min, 95°C); --, reaction with buffer W.
Telomere Maintenance and/or Protection Require Their Physical Association with the Nucleolus

In A. thaliana, telomeres tend to associate with the nucleolus (Armstrong et al., 2001; Franzé et al., 2002; Roberts et al., 2009). Consequently, we expect subtelomeric regions to be near the nucleolus, as shown previously by DNA FISH (Schubert et al., 2012). Our data demonstrate that at least 100 kb of each region flanking the telomeres strongly associate with the nucleolus. This association may have an effect on genes present in these regions. 39% of highly enriched NAD genes in Col-0 (No/N > 3) are distributed in these subtelomeric regions, whereas they represent less than 1% of the genome. The biological function of telomere nucleolar clustering remains unknown, but some studies have indicated a link between telomere biology and the nucleolus (reviewed in Dvoračková et al., 2015; Pederson, 1998; Schubert et al., 2014)). In human cells, the telomerase reverse transcriptase (TERT), which catalyzes reverse transcription of the telomerase RNA template into telomeric repeats, is activated in the nucleolus during S phase (Jády et al., 2006; Lermontova et al., 2007). In A. thaliana, a preferential nucleolar accumulation of telomere repeat-binding (TRB) MYB-like proteins was shown (Dvoračková et al., 2010). In addition, the telomerase RNA-binding protein dyskerin, AtNAP57/CBF5, and AITERT accumulate in the plant nucleolus (Kannan et al., 2008; Lermontova et al., 2007).

NAD identification in the nuc1 mutant revealed a decrease in telomere-nucleolus association. At the same time, we demonstrate that telomeres are shortened in the nuc1 mutant. Previous work demonstrated the important role of nucleolin in RNA organization and biogenesis (reviewed in Durut and Sáez-Vásquez, 2015)). However, all telomeres are affected in nuc1, so the proximity of rRNA genes on a NOR-bearing chromosome cannot explain telomere shortening. Subnucleolar structures show profound changes in nuc1 mutants, such as the loss of fibrillar centers (FCs), reductions in the dense fibrillar component (DFC), as well as an alteration of the granular component (GG) (Pontvianne et al., 2007). FCs, DFCs, and GCs are subnucleolar structures that are conserved in most eukaryotes and that reflect various steps of ribosome biogenesis (reviewed in Stepinski, 2014; Thiry and Lafontaine, 2005). The nucleolar disorganization observed in nuc1 mutants reflects the effect of these mutations on rRNA gene regulation. But nuc1 mutants also affect non-ribosomal nucleolar functions. CoIP TRAP experiments indeed argue in favor of a direct role of NUC1 in telomere biology. Whether NUC1 interacts directly or indirectly with the telomerase holoenzyme will have to be demonstrated by additional experiments. In addition, we cannot conclude whether telomere shortening is a cause or a consequence of telomere mislocalization. However, telomere clustering is not specific to A. thaliana. In budding yeast, telomeres cluster in foci at the nuclear periphery in cycling cells (Meister and Taddei, 2013). In quiescent cells, a lack of carbon source is followed by telomeres clustering into a unique focus in the center of the nucleus (Guidi et al., 2015). Although we do not have direct evidence to show it, these data argue in favor of a model where telomere shortening is a consequence of telomere mislocalization, probably because of the absence of NUC1. Combined with previous studies, our work strongly suggests a role for the nucleolus in the biology of telomeres.

Experimental Procedures

**Plant Materials and Growth Conditions**

Seeds corresponding to the nuc1-1 and nuc1-2 (referenced to as nuc1 throughout the manuscript) plants lines (SALK_035350 and SALK_002764, respectively) were reported previously and are available through the Nottingham Arabidopsis Stock Centre (NASC). Seeds of the nuc2-2 mutant (SALK GABI_17D01) and nuc2:NUC2 complemented line were described in Durut et al. (2014). Third generations of the knockout mutants fas1-4 (SAIL_662_D10) and fas2-4 (SALK_032298) are used in Figure 7 and were described in Exner et al. (2006). For FANoS, wild-type Col-0 expressing the FIB2::YFP fusion protein was described in Pontvianne et al. (2013). The nuc1-1 plants were crossed with Col-0 FIB2::YFP to introgress the nucleolar marker in the nuc1-2 mutant background. All plant material used here was grown in control growth chambers on soil at 21°C with a daylight period of 16 hr/day.

**Nuclear and Nucleolar DNA Preparation and Sequencing**

1 g of leaves from 3-week-old FIB2::YFP plants were fixed for 20 min in 4% formaldehyde in Tris buffer (10 mM Tris-HCl [pH 7.5], 10 mM EDTA, and 100 mM NaCl) and washed twice for 10 min in ice-cold Tris buffer. Washed leaves were minced with a razor blade in 1 ml of 45 mM MgCl2, 20 mM 3-(N-morpholino)propanesulfonic acid (MOPS; pH 7.0), 30 mM sodium citrate, and 0.1% Triton X-100. The homogenate was filtered through 30-μm mesh (PARTEC CellTrics) and subjected to FACs to sort nuclei or sonicated using a Bioruptor (three 5-min pulses, medium power; Diagenode) to liberate nucleoli that were then sorted by FANoS. Sorting of nuclei or nucleoli was triggered by the FIB2::YFP signal using a BD FACS Aria II. Sorted nuclei or nucleoli were treated with RNase A and proteinase K prior to purification and concentration using the ChIP DNA Clean & Concentrator kit (Zymo Research). DNA libraries were generated via the Nextera XT DNA sample preparation kit (Illumina) according to the manufacturer’s instructions and were then subjected to high-throughput paired-end 2 x 125 nt sequencing on a Hiseq 2500 apparatus (Illumina). Around 40 million clusters were recovered from the sequencing for each sample.

**Cytogenetic Analyses**

DNA FISH and DAPI-stained nucleus analyses were performed using nuclei from leaves of 3- or 4-week-old plants as described previously (Pontvianne et al., 2012). The 45S rRNA gene probe was generated by PCR on total genomic DNA from the Col-0 wild-type and corresponds to the region flanking the 45S rRNA gene transcription initiation site (from --223 to +243). The telomere-specific probe was generated by PCR on total genomic DNA from the Col-0 wild-type with the primers 5Telo (TTTAGGGTTAGGGTTAGGGTTAGGGTTAGGG) and 3Telo (CCCTAAACCTTAAACCTTAAACCTTAAACCTTAAAC). Hybridization and post-hybridization washes were performed as described previously (Durut et al., 2014) using the antibody anti-centH3 (HTR12 NBP1-18694, Novus Biologicals).

**Evaluation of Telomere Lengths using TRF and PETRA Analyses**

Nucleon Phytopure genomic DNA extraction kits (Illustra) were used for DNA extraction according to the manufacturer's instructions and were then subjected to Southern hybridization with the [32P]-labeled telomeric probe TR4C (CCCTAAACCTTAAACCTTAAACCTTAAAC). DNA libraries were generated using the ChIP DNA Clean & Concentrator kit (Zymo Research). DNA libraries were then sorted by FANoS. Sorting of nuclei or nucleoli was triggered by the FIB2::YFP signal using a BD FACS Aria II. Sorted nuclei or nucleoli were treated with RNase A and proteinase K prior to purification and concentration using the ChIP DNA Clean & Concentrator kit (Zymo Research). DNA libraries were generated via the Nextera XT DNA sample preparation kit (Illumina) according to the manufacturer’s instructions and were then subjected to high-throughput paired-end 2 x 125 nt sequencing on a Hiseq 2500 apparatus (Illumina). Around 40 million clusters were recovered from the sequencing for each sample.

**Bioinformatic and Statistical Analyses**

For each library, 30–50 million reads were obtained, with 85%–90% of the bases displaying a Q score of ≥ 30, with a mean Q score of 38, as assessed with
Fastqc. Thereafter, filtering out of reads corresponding to chloroplastic, mitochon- 
drial, and rRNA genes was performed with bowtie2 (Langmead and Salzberg, 2012). The remaining reads were mapped against the TAIR 10 genome with bowtie2 in sensitive local mode and no mismatch. TEs were analyzed according to the annotation published in Flutre et al. (2011). Quantification by 100-kb windows was made with bedtools software (http://bedtools.readthedocs.org/en/latest/). Regions with a fold change No/N superior to 2 are tagged “differentially covered” (DC). The data are presented in Data S5. Total RNA was extracted from three pools of 3-week-old Arabidopsis plant leaf tissues of wild-type Col-0 or nuc1? mutant using TRIzol reagent (MRC). Sequencing was performed by the Montpellier Genomix (MGX) facility (Mont- pellier) using a Hiseq 2000 to generate 1 × 51-bp-long reads. Illumina reads from non-stranded, polyA+ RNA deep sequencing libraries were aligned to the A. italiana TAIR10-annotated genome reference using Tophat2, Cufflinks, Cuffmerge, and Cuffdiff (Langmead and Salzberg, 2012).

The Z test calculation for two population proportions was used to determine whether the data differ between wild-type Col-0 and the nuc1? mutant in Figures 2A, 3D, 4E, and 6D.

ACCESS NUMBERS

The accession numbers for the DNA-seq and RNA-seq data reported in this paper are NCBI: SUB1340932 and BioProject: PRJNA312431, respectively.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, five figures, and five data files and can be found with this article online at http://dx.doi.org/10.1016/j.celrep.2016.07.016.

AUTHOR CONTRIBUTIONS

M.C. performed most bioinformatic analyses. N.D. and V.P. realized the telo- 
mer shortening analyses shown in Figure 7. K.J., S.S., and M.F. realized and 
rendered the data. F.P. designed, performed, and analyzed all ex-
periments except that shown in Figure 7 and wrote the manuscript.

ACKNOWLEDGMENTS

The authors are grateful to Eric Lasserre for help with TE analyses, Pascale Co-

della for logistic support, Claire Picart for help with confocal microscopy, 
Todd Blevins for correcting English, and Marie Mirozou for fruitful discussions. We also thank the flow cytometry facility of Montpellier RIO Imaging. This work was supported by CNRS, ANR JCJC.NucleoReg (ANR-15-CE12-0013-01) and by BQR2014 (UPVD), LAnoS (to F.P.), ANR SubCell (SV52E2_SUBCELIF 087217) (to J.S.), and GACR 16-01137S (to J.F.). The international collaboration between France and the Czech Republic is supported by the Barrande program (to J.S. 35626NL) and J.F. (7AMB16FR014). This work was initially supported by NIH Grant GM60380 (to C.S.P.). C.S.P. is an Investigator of the Howard Hughes Medical Institute and the Gordon and Betty Moore Foun-
dation. The international collaboration between the laboratories of C.S.P. and J.F. is funded by the Ministry of Education, Youth, and Sports of the Czech Rep-

country under the project CEITEC 2020 (LQ1601) and KONTAKT II (LH15189).
