The material-based studies examine through computation and physical prototyping layered composites for thermal responsive building envelopes. Focus is placed on surveying and computing a large series of materials across four groups, for then to test these materials from factors of solar energy reception capacities, internal heating methods, heat isolation coatings and layer bonding. An oak-polyethylene structure is developed based on the first studies and further tested towards implementation as part of an adaptive envelope demonstrator, with these studies focused on fabrication and assembly methods. Results of the developed, tested and applied composite as part of an adaptive envelope shows that the environmental-material composite is strongly influenced by colour and direct solar radiation exposure. This in turn allow a material-fabrication approach to program a responsive system driven by exergy. Reinforcing the responsive reaction of the composite by internal heating does not advance the performance, as coatings are needed to maintain the heat inside the material, which adds weight and isolate the composite from the thermal environment that otherwise is intended to provide the energy for driving the responsive behaviour. INTRODUCTION

This work and paper are focused on how materials can be combined into thermal responsive composites. Through the focus on material properties, assembly processes and thermal energy distribution in the composites, the study contributes to new understanding of the thermal reactive performance of layered materials. In this way, the work is intended as foundational research for intrinsic responsive and adaptive architectural surfaces, which are driven by material-environmental properties and interactions, in contrast to extrinsic mechanically actuated systems.

Previous research on material based responsive systems can be seen by thermodynamic (Foged and Pasold, 2015, 2016) and hydrodynamic (Correa et al 2013, Reichert et al, 2015, Raviv et al, 2014) studies, where both direct (material as actuator and en-
METHODS

The study uses a hybrid approach of material surveying, categorization, combinatorial analysis and physical prototyping. Each method is a stepwise delineation and filter the research of responsive performance based on composition of material layers.

Material surveying

The background on potential solutions of this work is a data collection surveying of a large set of materials to understand through computed combinatorial analysis the material responsive performance of a multitude of resultant composites. Additionally, increased understanding of connectivity between layers is important to utilise the composite’s responsive properties. Bonding studies with different adhesives of material layers and internal/external heat activation of layers are studied to understand both fabrication constraints and environmental and system activation of thermal-based responsive composites.

The paper presents firstly the survey and computed combinatorial analysis of approximately 200 materials, across 4 material groups. Following the categorization and understanding of materials through computed models, ten materials are selected for physical prototyping studies, where composites are fabricated to investigate the physical bending when exposed to actuation under gravity and thermal gradients. Additionally, the paper illustrates how a selected composite can be applied in an auxiliary adaptive envelope and installed as an on-site full-scale demonstrator. This effort points to the potentials of combining material-environmental responsive structures with mechanical-microprocessor driven mechanisms for coupled response properties.

Lastly, a discussion of the material studies, their relevant integration as architectural responsive surfaces and future outlook is presented.
Deflection of composite materials are calculated as bi-materials, but consist in reality of more layers, including 1-2 binding layers, which affect the properties of the composite structure in terms of strength, elasticity and thermal conductivity. The responsive bending can be positive and negative in direction depending on layer composition.

Prototyping Studies
Ten materials are chosen for physical prototyping studies, including Oak, Walnut, Pine, Polypropylene (PP), Polyethylene (PE), Polyvinylchloride (PVC), Copper, Aluminium, Bronze and Styrofoam. The materials are then combined to study the adhesive properties between low and high energy surfaces, their response to heat change and how heat can be induced between layers to increase responsive performance beyond the temperature change created by micro-climatic changes in proximity to the composites, as studied previously. A part of these studies are materials placed in the sun to measure the change of surface temperature as a result of solar radiation and material properties, which effectively drives the geometric responsive changes. This study gives an indication of the relative energy build-up in respect to material surface characteristics. As the study is aimed for potential applications in both indoor and outdoor environments, measurements were conducted outside to understand the minimum relative difference between materials, due to the added cooling effect of the materials from air movement. The study was conducted on a flat horizontal roof, with isolation between materials and the roof surface, in Copenhagen on 25 May, with a semi-cloudy sky, ambient temperature of 21 degrees Celsius and wind velocity of 4 m/s,

DESIGN EXPERIMENTATION

The experimentation with designing and making composites has been based on a project of creating a full scale 3x10 metre adaptive auxiliary building envelope. The focus of this paper, on the material studies for intrinsic driven responsive membranes, has been conducted in parallel to developments of a sensor-processing-actuation system and behavioural studies of the membrane-space-occupancy interactions. Due to the extent of the material studies and other aspects of the entire project, a full account of other aspects than the material studies are to be found in associated paper publications. Following the focus of the material studies in this paper, the experimentations described above where expanded to investigate cutting methods for the layer-assembled membranes. A series of material prototyping studies, as described above, revealed a high responsive bending performance and operational durability of the thin membrane (1.5 mm) when combining Oak (0.5 mm) and PE (1 mm). Oak has low thermal expansion parallel to the grain and PE has a high thermal expansion, as an isotropic material, in all directions. Combining materials with low and high energy surfaces require priming (3M Primer 94) the low energy surface to allow adhesion to the high energy surface through a non-core high bond adhesive ‘tape’ (3M VHB LSE.

The dimensions of the membrane responsive panels were developed through simulating the amount of solar energy passing through the composite membrane as a function of temperature variations, described and documented in the associated publication. The design experimentation of the material studies is then followed by investigating methods for cutting the generated membrane shapes, which ultimately becomes the material responsive elements of the envelope. For these studies, a Zund Eurolaser XL-1600 flatbed industrial machine is used with three different tool heads; a laser, a vertical oscillating knife, and a 1-2 mm wide mill head. While the laser cuts through the composite (oak-glue-primer-PE), it melts the PE, which then ‘travels’ towards the oak layer and creates edges and surface on the oak with unintended plastic coating. Using a knife method allows clean cuts, particularly along the grain of the oak, but fails to create a small gap, which is required when the composite attempts to bend out of its plane during thermal changes. Without the gap, friction is caused, reducing or prohibiting the bending action. Using a 1 mm drill head creates both a clean, non-melted and friction less result. Only drawback with this method is the accumulated PE on the drill head, due to heated material, which may cause reduced cutting ability, leading to mill head fracture, figure 5. In addition, the application of a bonding adhesive without a core material, only including bonding material when rolled on, reduces fabrication problems, as only a minimum of material interfacing between the primary material layers are applied, figure 4.

Following the making of the composite panel, pattern cutting and integration into the mounting frames, onsite studies were conducted to understand and demonstrate the responsive performance of an exergy-based geometric bending of composite elements. The envelope panels are located on the inside of a glass pane, facing south-east, in a dense urban environment in Copenhagen. This means that the composites are effected by solar radiation on limited and specific hours of the day, that they are not cooled by air movement, and that they are embedded into an interior environment which ambient air is automatically kept at approximately 22 degrees Celsius from HVAC systems control. This means that the bending performance of the membrane is isolated to the solar radiation in relatively short and specified periods allowing a good reading of the solar radiation to material performance relations. As shown by the colouration/temperature studies above, dark materials have a significantly higher surface temperature, which increase response performance per degrees Celsius change. Hence, a black PE was used with the oak to form the primary material layers of the composite for the onsite demonstrator studies, figure 5, 6, 7 and 8.

RESULTS AND CONCLUSION

The studies include a series of quantitative and qualitative results and conclusions.

- When solar radiation is the driver for actuation, colouration has a large impact on responsive performance. Comparative analysis measuring a range of materials show this, and measurements on the demonstrator support this, with the black PE side reaching 57 degrees Celsius, compared to the ambient temperature of 22 degrees Celsius. The specific degree of colour impact on performance is determined by the composite primary materials, the bonding structure, the geometric relations of size and thickness and the onsite explicit exposure to the solar energy.

- Coating the composites to increase thermal build-up by internal heating, significantly/completely reduces the ability to drive the actuation through the solar radiation as an exergy-based strategy. In addition, the coating adds weight to the active composite, which decreases response performance due to the extra load needed to be moved by the active composite. Hence, a coating/isolation approach to the responsive system must be taken when developing composites for the specific purpose.

- The composites developed hold some resistance to composite response behaviour fatigue. More than 150 days after fabrication, the composites are changing bending form and no delamination has been detected of the +400 bending elements. While the composites have not been tested in a climate laboratory where temperature constantly is changed up and down under regulated conditions, the composites have been placed in windows where they have been exposed to environmental conditions similar to possible applications in practice.

- The responsive operation of the composite is silent. This is favourable in spaces where en-
environmental sound levels are low, such as offices, study environments etc. Combined with the subtle and relative slow moment of the elements, the responsive membrane is perceived as a low-invasive active building layer.

- Given that the membrane is driven by solar environmental dynamics, it is limited to performance that are encoded into the membrane from its fabrication. Hence, such systems are not open to reprogramming of behaviour, which suggest the possibility of coupling to human and motorised systems, which may react to unforeseen or new conditions in a specific environment.

**DISCUSSION**

The presented studies contribute to the understanding and application of material driven responsive performance membranes, through a large material study and resultant catalogue of composite behaviours. It also illustrates how these can be bonded and cut into specified membranes reacting from thermal changes in an environment. The study also finds that additional activation of the responsive capacities through inducing heat between layers and insulating the composite to improve and maintain heat build-up are problematic. This is also due to the wire reducing bonding between layers, resisting bending (depending on wire layout). Further studies into internal heating and regulating of stimuli for responsive behaviour may however change the instrumentality of the responsive material system into a more open and adaptive operated system based on unknown conditions when the envelope is fabricated. Hence, this may be an option for controlling bending through an MCU with embedded behaviour controls, yet, enhancements of this approach through insulation of the composites also means isolation from the thermal microclimatic environment which activate responsive behaviour without applying electrical energy. For this reason, the study points to coupled, or hybrid, systems, where intrinsic material-driven response behaviour is paired with another response system, such as proposed in the general project, allowing material-driven and MCU-driven systems to operate in combination without limiting the capacities of each their specific strengths as environmental adaptive mechanisms for architectural envelopes.
