Abstract. We study colloidal ordering and disordering on two-dimensional periodic substrates where the number of colloids per substrate minima is two or three. The colloids form dimer or trimer states with orientational ordering, referred to as colloidal molecular crystals. At a fixed temperature such that, in the absence of a substrate, the colloids are in a triangular floating solid state, upon increasing the substrate strength we find a transition to an ordered colloidal molecular crystal state, followed by a transition to a disordered state where the colloids still form dimers or trimers but the orientational order is lost. These results are in agreement with recent experiments.

Colloidal particle assemblies in two dimensions (2D) are an ideal system to study ordering and melting, since quantities such as diffusion, dislocation dynamics, and local ordering can be directly observed, which is typically not the case for atomic and molecular systems. Repulsively interacting colloids on a smooth substrate in 2D form triangular arrangements at high density or low temperatures, with hexatic or liquid states at lower densities. Optical techniques such as interfering laser arrays have created one-dimensional (1D) line-like potentials which attract the colloids. Experimental studies of periodic 1D potentials find a remarkable laser-induced freezing transition, where for zero substrate strength the colloids form a disordered liquid, but with increasing substrate or laser strength there is a transition to a frozen ordered state. This laser-induced freezing was studied with density-functional theory and simulations. These theoretical works also found that for increased substrate strength, the frozen state can show a reentrant disordering transition to a 1D modulated liquid. This reentrance was similar to that subsequently observed in experiments. Further theoretical studies have mapped additional properties of this system, and some of these predictions have also been confirmed in experiments. The reentrant disordering occurs because, as the substrate strength is gradually increased, the system becomes effectively 1D. The fluctuations are enhanced for lower dimensionality and can lead to the formation of a 1D liquid.

More recently, colloidal assemblies interacting with 2D periodic substrates have been investigated. Simulations of colloids on 2D periodic substrates have considered the case where the number of colloids is an integer multiple of the number of potential minima. In this case, multiple colloids sit in each potential minimum and form dimer, trimer, or higher states depending on the filling. These colloidal states can have an additional orientational ordering and have been termed colloidal molecular crystals (CMCs) in analogy with molecules forming crystalline states with orientational ordering of the molecules. Three phases appear in the simulations: a high temperature liquid regime, a low temperature orientationally ordered CMC, and an intermediate disordered CMC phase where the orientational order is lost but the colloids remain trapped in each minimum, rotating freely but not diffusing. Experiments on 2D periodic optical traps with three colloids per potential minimum confirmed the existence of the three phases. In these experiments, the temperature and density of the system were fixed and the intensity of the traps was increased by tuning the laser power. Here, as a function of increasing substrate strength, the initial state was a liquid, followed by a transition to an orientationally ordered CMC and, at higher strengths, a transition to a disordered CMC. This reentrant disordering is similar to that found for 1D periodic modulated substrates. In previous simulations of the CMC, conclusive evidence for this reentrance was not presented.

In this work we measure the diffusion of colloids from their traps and also the degree of rotational order between molecules in adjacent wells. We then numerically map the phase diagram as a function of substrate strength. We observe four phases, floating (triangular) solid, rotationally ordered and disordered colloidal molecular crystal, and liquid. The transition to the liquid state rises monotonically in temperature with the substrate potential strength, but the transition from the ordered to the disordered CMC phase first increases and then decreases in temperature with increasing substrate strength. This leads to a striking feature of the phase diagram: clear evidence for a reentrant disordered CMC as a function of substrate strength.

We perform a Langevin simulation of a 2D system with periodic boundary conditions in the $x$ and $y$ directions, as in previous work. There are $N$ colloids
interacting with a 2D periodic substrate which has $M$ minima. We focus on the two cases $N/M = 2$ and 3. The overdamped equation of motion for a single colloid $i$ is

$$\frac{d\mathbf{r}_i}{dt} = \mathbf{f}_i + f_s + f_T,$$  

where $\mathbf{f}_i = \sum_{j \neq i}^N \nabla_i V(r_{ij})$ is the interaction force from the other colloids, which we take to be a Yukawa or screened Coulomb form, $V(r_{ij}) = (Q^2/|\mathbf{r}_i - \mathbf{r}_j|) \exp(-\kappa|\mathbf{r}_i - \mathbf{r}_j|)$. Here $Q$ is the charge of the particles, which we set to 1.0, $1/\kappa$ is the screening length, and $\mathbf{r}_i$ is the position of particle $i$. We consider a square substrate with a lattice constant $a$ with a force $f_s = A \sin(2\pi x/a)\hat{x} + A \sin(2\pi y/a)\hat{y}$. In this work we keep $a$ fixed and vary $A$. The screening length is fixed at 1.5$a$. The thermal force $f_T$ comes from Langevin kicks with the properties $<f_T> = 0$ and $<f_T(t)f_T(t')> = 2k_B T \delta_{ij} \delta(t-t')$. The initial colloidal positions are obtained by annealing from a high temperature and gradually cooling to zero.

We first concentrate on the case $N/M = 2$. As a function of $T$ and $A$, we find the four phases illustrated in figure 1. For very low $A$ and $T$, we find a floating triangular lattice as shown in figure 1(a), where the substrate is weak enough that the elastic interaction of the colloids dominates and they form a triangular lattice. At high enough $T$, for all $A$ we find a modulated liquid where the colloids are disordered and have a large diffusion constant, as shown in figure 1(b). For low $T$ and large enough $A$, the orientationally ordered CMC of figure 1(c) forms. Each potential minima captures two colloids and the colloid dimer orientation alternates from vertical to horizontal. For larger $A$ and $T$, a disordered CMC phase occurs in which the colloids are still fixed to the potential minima but long range orientational ordering is lost, as seen in figure 1(d).

We use various measures to identify the different phases in the $T$ vs $A$ phase diagram. In order to find the ordered to disordered CMC transition, we measure the rotational disorder fraction $F$ of the particles. To determine $F$, we define each dimer to be horizontally or vertically oriented depending on whether the $x$ or $y$ component of the vector joining the two colloids is larger. $F$ is then defined as the fraction of the dimers which differ from the ordered CMC configuration of alternating vertical and horizontal. In figure 2 we plot $F$ vs $T$ for different values of $A$.

To distinguish between the CMC phases and the liquid phase, we measure the diffusion $D$ of the particles by calculating the average of the square of the distance traveled by the particles from their initial positions after a large, fixed number of time steps. In figure 3, we plot $D$ as a function of temperature $T$ for different potential depths $A$. The temperature at which the colloids escape their wells rises monotonically with $A$. For high values of $A$, the colloid dimers are no longer in a rotationally ordered configuration before they leave the wells, showing the existence of the disordered CMC. We measured the transitions for several different initial starting configurations of the colloids and found that the results were unchanged.

In figure 4 we plot the transition lines from the ordered CMC to the liquid, floating solid, and disordered CMC states, obtained using the measures illustrated in figure 2 and figure 3. Here, the range of temperature over which the ordered CMC phase exists increases in extent as $A$ increases from zero, reaching a maximum width at $A = 0.75$. As $A$ is further increased above $A = 0.75$, the width in $T$ of the ordered CMC phase decreases. A transition to a disordered CMC for $A > 0.5$ replaces the transition to the liquid phase for $A < 0.5$. This decrease shows a slight nonlinearity. The transition line between the disordered CMC and the liquid moves to higher temperature roughly
Figure 1. The colloidal configurations for a square periodic substrate in 2D. The circles indicate the location of the potential wells. (a) For a sufficiently weak substrate potential, at low temperatures, (here $A = 0.0, T = 0.0$) the colloids form a floating triangular lattice, which has some mild distortion (see text). (b) At high enough temperature, for any substrate potential, (here $A = 1.0, T = 5.0$) the colloids form a liquid. (c) For all but the smallest potentials, at low temperatures, (here $A = 1.0, T = 0.0$) the colloids form a rotationally ordered solid. (d) For large enough substrate potentials, an intermediate (here $A = 1.0, T = 2.3$) disordered CMC phase exists between the rotationally ordered solid phase and the liquid phase.

Figure 4 shows a clear disordering reentrance. For a fixed $T = 1.80$, the colloids are in a liquid state at $A = 0$. A transition to the ordered CMC state occurs at $A \approx 0.19$, while a transition to the disordered CMC state occurs at $A \approx 1.07$. This sequence of transitions for increasing substrate strength is exactly what is seen in experiment [10].

The initial increase in the disordering temperature with substrate strength occurs due to the fact that some finite substrate strength is required to confine the colloids, which are either in a floating solid or liquid state in the absence of a substrate. When the potential is just strong enough to trap the colloids, the size of each dimer (the distance between the two colloids composing the dimer) is at its maximum, and the colloids are close to jumping out of the confining well. At a somewhat higher temperature, the colloids begin to diffuse; thus, as the potential strength increases,
Figure 2. Rotational disorder fraction vs temperature, for (from left to right) $A = 3.0, 2.0, 1.50, 0.25,$ and $0.50$. The transition line from ordered CMC to disordered CMC on the phase diagram in figure 4 is defined as the temperature at which $F = 0.4$. The transition temperature first increases from $A = 0.25$ to $A = 0.50$, but then decreases for larger $A$.

Figure 3. Diffusion vs temperature for (from left to right) $A = 0.25, 0.5, 1.0, 1.5, 2.0, 2.5,$ and $3.0$. The melting temperature is defined as the point at which $D$ first increases sharply, when the particles are no longer bound in the potential wells.
Figure 4. Phase diagram of temperature vs potential strength $A$. In region I the colloids form a floating solid of a triangular lattice. In region II the colloids form a liquid. In region III the colloids are in a rotationally ordered solid state. Finally, in region IV the colloids are in a solid state which has no rotational ordering. Circles indicate the transition to the ordered CMC as determined by the rotational disorder fraction $F$. Squares indicate the melting transition measured from the diffusion $D$.

The temperature at which diffusion begins also increases. We note that the cause of the orientational ordering of the dimers is their effective quadrupole moment. The energy of interaction between these moments is minimized when the dimers are oriented as in figure 1(c). The strength of the quadrupole moment is proportional to the square of the distance between the two colloids in a single potential minimum. As $A$ is increased, this distance decreases. If we approximate the well confining the colloids as a parabola, then the distance between the colloids in the dimer decreases by $\delta r \propto A$. As the strength of the quadrupole moment drops, thermal effects dominate the orientational ordering and the colloidal dimer begins to rotate, destroying the orientational ordering.

In figure 5 we show a blowup of the phase diagram from figure 4 for the region with small $A$. Here, we find that at low temperatures the elastic interactions between the colloids dominate over the substrate, and an almost triangular lattice forms. We call this a floating solid since the system is effectively frozen with no diffusion. In figure 6 we show the rotational disorder fraction plot for small values for $A$, which was used to identify the floating solid phase.

In order to show that the reentrant disordering is a general feature for CMC states we have considered other integer fillings as well. In figure 7 we plot the phase diagram using the same measures as in figure 4 for the case of $N/M = 3$ on a triangular substrate. This is the filling fraction used in recent experiments [10]. Here the ordered CMC is the same as found in earlier simulations [9]. The phase diagram has the same basic features as in figure 4, where $M/N = 2$ and dimers form in the wells. However, the critical temperatures are a bit lower, as is reasonable, and while the non-monotonic
Figure 5. Phase diagram of temperature vs $A$ at small $A$, highlighting the floating solid region.

Figure 6. Rotational disorder fraction $F$ vs temperature for (from left to right) $A = 0, 0.05, 0.06, 0.07, 0.10, 0.20, 0.30, \text{ and } 0.50$. For $A \leq 0.07$, the colloids are initially ($T = 0$) in a floating solid state. The rotational disorder fraction exceeds 0.4 for these values of $A$ at all temperatures.
(re-entrant) behavior of the rotational melting line is still clearly evident, the liquid at small $A$ does not extend as deeply below the peak in the rotationally ordered phase.

In conclusion, we have shown clear numerical evidence for reentrant disordering of colloidal molecular crystals on 2D periodic substrates for increasing substrate strength and fixed temperature, in agreement with recent experiments. We map out the temperature vs substrate phase diagram and show that four phases can occur: a high temperature liquid, a triangular floating solid, an orientationally ordered colloidal molecular crystal state, and a disordered colloidal molecular crystal state.
