Abstract

In this paper we show that given a max-plus automaton (over trees, and with real weights) computing a function $f$ and a min-plus automaton (similar) computing a function $g$ such that $f \leq g$, there exists effectively an unambiguous tropical automaton computing $h$ such that $f \leq h \leq g$.

This generalizes a result of Lombardy and Mairesse of 2006 stating that series which are both max-plus and min-plus rational are unambiguous. This generalization goes in two directions: trees are considered instead of words, and separation is established instead of characterization (separation implies characterization). The techniques in the two proofs are very different.

1 Introduction

Tropical automata is a nickname for weighted automata (automata parameterized by a semiring as introduced by Schützenberger [17]) over a tropical semiring. This is a particularly simple model of finite state automata that describe functions rather than languages. It exists in two forms, max-plus and min-plus automata. Essentially, a tropical automaton $\mathcal{A}$ is a non-deterministic automaton for which each transition is labelled by a real weight (or an integer, or a natural number, depending on the variants). This weight is extended into a weight for a run: the sum of the weights of the transitions involved. A max-plus automaton computes the function $[\mathcal{A}] : A^* \to \mathbb{R} \cup \{\perp\}$ which to an input word associates the maximum weight of an accepting run over the input, or $\perp$ if there is no accepting runs. If it is a min-plus automaton, minimum is used instead of maximum.

The use of tropical automata arises naturally in different contexts: max-plus automata have been used for modeling scheduling constraints (see for instance [4]) or worst case behaviors (see for instance [3] for computing the asymptotic worst case execution time of loops under the size-change abstraction); min-plus automata are used for optimisation questions (these are for instance used as a key tool in the decision of the star-height problem [6]). In all these situations, non-trivial decision procedures are used ([5, 12, 2]).

The starting point of this work is a result from 2006 of Lombardy and Mairesse:

\textbf{Theorem 1 ([13, 14])}. A map $f : A^* \to \mathbb{R} \cup \{\perp\}$ which is both definable by a min-plus and by a max-plus automaton is definable by an unambiguous tropical automaton.
Recall that an automaton is unambiguous if there is at most one accepting run per input\(^1\). Unambiguous automata form a very particular class of tropical automata. Most of the problems which are open or undecidable for general tropical automata are easily decidable for unambiguous automata: equivalence with another tropical automaton \([9]\), boundedness, sequentiality, description of the asymptotic behaviour \([1]\).

It is noteworthy that the decision of sequentiality actually applies to unambiguous automata and that algorithms described for larger classes (finitely or polynomially ambiguous), consist indeed in deciding first whether the tropical automaton is equivalent to some unambiguous one \([8, 7]\).

The above Theorem 1 belongs to a fascinating corpus of mathematical statements of the form ‘if \(X\) belongs both to class \(C\) and to class \(D\), then it belongs to class \(E\)’, where \(E\) is structurally simpler than both \(C\) and \(D\) (often \(D\) is some form of dual of \(C\)). An archetypical example arises in descriptive set theory: Suslin’s theorem states that

if a set is analytic and coanalytic, it is Borel.

Many other instances of this pattern exist. For instance in automata theory, if an infinite tree language is Büchi and its complement is Büchi, it is weak (Rabin’s theorem \([15]\)). This extends to cost-functions over infinite trees: if a cost-function over infinite trees is both B-Büchi and S-Büchi, it is quasi-weak ; over infinite words, it is even weak (Kuperberg and Vanden Boom \([10, 11]\)). For languages of infinite words beyond regular, if a language is \(\omega B\) and \(\omega S\) definable, then it is \(\omega\)-regular (Skrzypczak \([18]\)). In language theory, a language which is both \(\Sigma_2\) and \(\Pi_2\) definable is definable in the two variables fragment (Thérien and Wilke \([19]\)). Also, a language which is both the support and the complement of the support of a rational series over a field is regular \([16]\). This list continues on and on.

In many situations such statements arise in fact from a more general result of ‘separation’ (or of ‘interpolation’ in the logical terminology). For instance, Suslin’s theorem is the separation version of Suslin’s theorem: It states that

for \(X \subseteq Y\) with \(X\) analytic and \(Y\) coanalytic, then \(X \subseteq Z \subseteq Y\) for some Borel set \(Z\).

Such separation results imply the characterization version. For instance, Suslin’s result follows from Lusin’s theorem: take \(X = Y\) to be the set which is both analytic and coanalytic. Then \(X \subseteq Z \subseteq Y = X\) for \(Z\) Borel; hence \(X\) is Borel. This relationship is general. The results of Rabin, Vanden Boom and Kuperberg, and Skrzypczak, for instance, exist in a ‘separation variant’.

**Contribution**

The natural question that we answer in this work is thus:

Does there exist a separation version of Theorem 1 ?

In this paper, we provide a positive answer to this question. It takes the following form:

**Theorem 2** (separation for tropical tree automata). Given a max-plus automaton \(A_{\text{max}}\) and a min-plus automaton \(A_{\text{min}}\) such that\(^2\)

\[
[A_{\text{max}}] \leq [A_{\text{min}}],
\]

\(^1\) Note that when a tropical automaton is unambiguous, it makes no difference whether it is a max-plus or a min-plus automaton: It computes the same function.

\(^2\) In this statement, we assume that \(\bot\) is incomparable with other elements, and thus \([A_{\text{max}}]\) and \([A_{\text{min}}]\) have same support.
there exists effectively an unambiguous tropical automaton $A_{\text{sep}}$ such that

$$[A_{\text{max}}] \leq [A_{\text{sep}}] \leq [A_{\text{min}}].$$

Let us stress that the above theorem is established in the context of tropical automata over trees. Theorem 1 is now a corollary. Indeed, (a) tropical word automata are a particular case of tree automata over a ranked alphabet made of unary symbols only, plus a constant, and (b) assuming that $f$ is both accepted by a min-plus and by a max-plus automaton, then by Theorem 2, there exists a function $h$ accepted by an unambiguous tropical automaton such that $f \leq h \leq f$. Thus $f = h$ is accepted by an unambiguous tropical automaton.

Note that, though the result is a generalization, the proof of Theorem 2 is very different from the original one of Theorem 1.

Let us finally emphasize that particular care has been taken in order to obtain the result for real weights. Indeed, in the integer case (and as a consequence in the rational case), simpler techniques can be used that involve keeping in the finitely many states of the result automaton some explicit differences of partial weights up to a certain bound. Such a technique (as far as we know) cannot be used in the real case.

Other related work

The class of unambiguous tropical automata form an interesting subclass of tropical automata. In particular, equivalence is decidable, while the problem for max-plus or min-plus automata is undecidable [9]. Given a tropical automaton, deciding unambiguity is an open problem. It has been solved if the input automaton is finitely ambiguous in [8], and when it is polynomially ambiguous in [7].

Structure of the paper

This paper is organized as follows. In Section 2, we recall the standard definitions concerning trees, automata over trees, and tropical automata. In Section 3, we establish our main theorem of separation, Theorem 2. Section 4 concludes.

2 Definitions

We review in this section classical notions concerning terms, and then automata and tropical automata.\(^3\)

2.1 Terms and contexts

A ranked alphabet is a set $A$, the elements of which are called letters, together with a map rank from $A$ to $\mathbb{N}$. For $n \in \mathbb{N}$, let Terms$(n)$ be the set of terms of arity $n$ over the alphabet $A \cup \{1, \ldots, n\}$ in which $1, \ldots, n$ are seen as special letters of rank 0 that are used exactly once in each term. We call simply terms the terms of arity 0, and the set of terms is simply denoted Terms. We call context the terms of arity 1, and the set of contexts is simply denoted Contexts. Note that each letter $a$ of rank $r$ can naturally be seen as a term of arity $n$ consisting solely of a root labelled $a$ and children $1, \ldots, n$. The nodes of a term of arity $n$,

\(^3\) Note that this document incorporates internal links relating each notion used to its introduction. These have been generated using the \texttt{hyperref} package \texttt{knowledge}, and are usable in all PDF viewers (some do even offer an overview of the definition when hovering above a word). Any feedback welcome.
Nodes\((t)\) is the set of positions of the letters in the term. The root node is denoted root. A node labelled \(i\) for \(i = 1 \ldots n\) is called the \(i\)th-hole. The nodes that are not holes are called inner nodes. Given a node \(x \in \text{Nodes}(t)\), \(t(x)\) denotes the letter it carries. Given a letter of rank \(n\) and terms \(t_0, \ldots, t_{n-1}\), we denote by \(a(t_0, \ldots, t_{n-1})\) the term that has \(a\) as root, and as children from left to right \(t_0, \ldots, t_{n-1}\). The height of a term \(s\), denoted \(\text{height}(s)\), is the longest length of a branch, for the standard meaning of a branch. The size of a term \(s\), denoted \(\text{size}(t)\), is the number of nodes it has. Finally, given a context \(c\) and a term (resp. \(t\) another context), we denote \(c \circ t\) the term (resp. the context) obtained by plugging the root of \(t\) in the hole of \(c\).

### 2.2 Automata

A non-deterministic (tree) automaton (or simply an automaton) has a finite set of states \(Q\), an input ranked alphabet \(A\), a set of final states \(F\), and a transition relation \(\Delta\) that consists of tuples of the form \((p_0, \ldots, p_{n-1}, a, q)\) in which \(a \in A\) is a letter of rank \(n\), and \(p_0, \ldots, p_{k-1}, q\) are states from \(Q\).

A run of the automaton over a term \(t\) of arity \(n\) is a map \(\rho\) from \(\text{Nodes}(t)\) to \(Q\) such that for all inner nodes \(x \in \text{Nodes}(t)\) of children \(x_0, \ldots, x_{n-1}\), \((\rho(x_0), \ldots, \rho(x_{n-1}), t(x), \rho(x)) \in \Delta\). We shall write \(\rho(x)\) this transition. An accepting run is a run of the automaton such that \(\rho(\text{root}) \in F\). Given a term \(t\), \(t\) is accepted by the automaton if there exists an accepting run of the automaton over \(t\). The set of terms that are accepted is the language accepted by the automaton.

We slightly refine the terminology for easier use. Over a term, a run to state \(q\) is a run that assumes state \(q\) at the root. Over a context, a run from state \(p\) to state \(q\) signifies that the state assumed in the hole is \(p\), and the one assumed at the root is \(q\). An accepting run from \(p\) is a run from \(p\) to \(q\) for a final state \(q\).

An automaton is unambiguous if for all input terms \(t\), there exists at most one accepting run over it. Said differently, for all input terms \(t\), either there are no accepting runs over it, and the term is not accepted, or there is exactly one accepting run, and the term is accepted.

An automaton with weights\(^4\) \(A\) is a non-deterministic automaton together with a real weight for all transitions and all final states, i.e., a map weight from \(\Delta \cup F\) to \(\mathbb{R}\). Given a run \(\rho\) of the automaton, the weight of the run \(\text{weight}(\rho)\) is the sum of the weights of \(\rho(x)\) for \(x\) ranging over the inner nodes of \(\rho\). Given an accepting run \(\rho\) of the automaton, the weight of the accepting run \(\text{weight}^{\text{acc}}(\rho)\) is the sum of the weight of the run and \(\text{weight}(\rho(\text{root}))\).

Tropical automata refer in this work to one of two forms of automata: min-plus automata and max-plus automata defined as follows. A min-plus automaton \(A\) is an automaton with weights that computes a function:

\[
\begin{align*}
\text{[}A\text{]}_{\text{min}} : \text{Terms} &\rightarrow \mathbb{R} \cup \{\bot\} \\
\text{[}A\text{]}_{\text{min}}(t) &\left\{ \begin{array}{ll}
\bot & \text{if there are no accepting runs of } A \text{ over } t, \\
\min \{ \text{weight}^{\text{acc}}(\rho) \mid \rho \text{ accepting run of } A \text{ over } t \} & \text{otherwise,}
\end{array} \right.
\end{align*}
\]

in which \(\bot\) is a symbol that we understand as ‘undefined’ (it appears classically as an absorbing element for + which is larger than all \(x \in \mathbb{R}\), i.e., the zero of the tropical semiring). A max-plus automaton is defined in an identical manner, but the semantics \([A]_{\text{max}}\) is now defined using max instead of min. Since it is always clear from the context, we denote simply

\(\text{[}A\text{]}_{\text{min}}\).

---

\(^4\) This is not the a weighted automaton, which is parametrized by a semiring and not a monoid. This definition serves here just for holding the structure of our tropical automata irrespective of whether these are min-plus or max-plus.
by \([A]\) either \([A]\)_{\text{min}} or \([A]\)_{\text{max}} depending on whether \(A\) has been declared as a min-plus or as a max-plus automaton.

An unambiguous tropical automaton \(A\) is a tropical automaton that has an unambiguous underlying automaton. Note that in this case, \([A]\)_{\text{max}} = \([A]\)_{\text{min}} and hence we call it simply tropical automaton and do not have to specify whether it is a min-plus or max-plus.

### 3 Separating tropical automata

#### 3.1 Statement and structure of the proof

The goal of this section is to prove our main theorem:

**Theorem 2** (separation for tropical tree automata). Given a max-plus automaton \(A_{\text{max}}\) and a min-plus automaton \(A_{\text{min}}\) such that

\[ [A_{\text{max}}] \leq [A_{\text{min}}], \]

there exists effectively an unambiguous tropical automaton \(A_{\text{sep}}\) such that

\[ [A_{\text{max}}] \leq [A_{\text{sep}}] \leq [A_{\text{min}}]. \]

From now on, we fix the ranked alphabet \(A\), a max-plus automaton \(A_{\text{max}}\) and a min-plus automaton \(A_{\text{min}}\):

\[ A_{\text{max}} = (Q_{\text{max}}, A, F_{\text{max}}, \Delta_{\text{max}}, \text{weight}_{\text{max}}) \quad \text{and} \quad A_{\text{min}} = (Q_{\text{min}}, A, F_{\text{min}}, \Delta_{\text{min}}, \text{weight}_{\text{min}}) \]

such that

\[ [A_{\text{min}}] \leq [A_{\text{max}}]. \]

It will be convenient in what follows to consider a single automaton with weights \(A\) constructed as the disjoint union of \(A_{\text{max}}\) and \(A_{\text{min}}\) (of course, it should be neither seen as a min-plus automaton nor as a max-plus automaton). Formally, we assume without loss of generality that \(Q_{\text{max}}\) and \(Q_{\text{min}}\) are disjoint, and we set

\[ Q = Q_{\text{min}} \cup Q_{\text{max}}, \quad F = F_{\text{max}} \cup F_{\text{min}}, \quad \Delta = \Delta_{\text{max}} \cup \Delta_{\text{min}}, \]

and

\[ \text{weight}(v) = \begin{cases} \text{weight}_{\text{max}}(v) & \text{for } v \in \Delta_{\text{max}} \cup F_{\text{max}} \\ \text{weight}_{\text{min}}(v) & \text{otherwise}. \end{cases} \]

The rest of this section is devoted to the proof of Theorem 2, and is organized as follows. In Section 3.2, we use some classical automata constructions for accessing in an unambiguous manner the reachable and productive states (Lemma 3). The combinatorial core of the proof is contained in Section 3.3 in which we study how the values of the automata may evolve in a context (Lemma 9), and use it for showing how terms can be substituted while preserving separability (Corollary 11). We finally provide the construction of the automaton \(A_{\text{sep}}\) in Section 3.4, and establish its correctness (Lemma 14). This concludes the proof of Theorem 2.

---

5 In this statement, we assume that \(\perp\) is incomparable with other elements, and thus \([A_{\text{max}}]\) and \([A_{\text{min}}]\) have same support.
3.2 Reachable and productive states

An ingredient which is necessary in the proof is that the automaton we construct is always ‘aware’ of what are the states that may lead to an accepting run to the root. This section is concerned with this aspect, and involves only completely standard techniques for tree automata.

Given a term $t$, set $\text{Reach}(t) \subseteq Q$ to be the set of states $p$ such that there is a run over $t$ to $p$. We call such states reachable in $t$. Given a context $c$, set $\text{Prod}(c) \subseteq Q$ to be the set of states $p$ such that there is an accepting run from $p$. We call such states productive in $c$. We finally set $\text{Reachable} = \{ \text{Reach}(c) \mid c \in \text{Contexts} \}$ and $\text{Productive} = \{ \text{Prod}(t) \mid t \in \text{Terms} \}$.

We now construct an automaton $A_{\text{pro}} = (Q_{\text{pro}}, A, F_{\text{pro}}, \Delta_{\text{pro}})$ that computes the productive states at each node of a term. The states are $Q_{\text{pro}} = \text{Reachable} \times \text{Productive}$. The final states $F_{\text{pro}} = \text{Reachable} \times \{ F \}$, and for all letters $a$ of rank $n$, the automaton has a transition of the form $(\left( R_0, P_0 \right), \ldots, (R_{n-1}, P_{n-1}), a, (R, P)) \in \Delta_{\text{pro}}$ whenever

$R = \{ r \in Q \mid (r_0, \ldots, r_{n-1}, a, r) \in \Delta, r_j \in R_j \text{ for all } j \}$, and

$P_i = \{ r_i \in Q \mid (r_0, \ldots, r_{n-1}, a, p) \in \Delta, r_j \in R_j \text{ for } j \neq i, p \in P \}$ for all $i = 0 \ldots n - 1$.

In the above definition, the constraint on $R$ induces the computation in a bottom-up deterministic way of the set of states that are reachable from the term below. The constraint on $P_i$ computes similarly in a top-down deterministic way the set of states that are productive in the context above. We do not prove the correctness of this construction further. The important aspects of this construction are summarized in the following lemma.

Lemma 3. For all $P \in \text{Productive}$ and all terms $t$, there exists one and one only run of $A_{\text{pro}}$ over $t$ to a state of the form $(R, P)$ for some $R \in \text{Reachable}$. And furthermore, $R = \text{Reach}(t)$.

For all $R \in \text{Reachable}$ and all contexts $c$, there exists one and one only accepting run of $A_{\text{pro}}$ over $c$ from a state of the form $(R, P)$ for some $P \in \text{Productive}$. And furthermore, $P = \text{Prod}(c)$.

3.3 The central pumping lemma

In this section, we establish the key Corollary 11. The central concept here is to understand what it does for the value computed by $A_{\text{max}}$ and by $A_{\text{min}}$ to substitute a subtree for another subtree. And more precisely, we devise sufficient conditions such that, after performing the substitution, the values of the two automata gets closer one to the other, up to some shifting.

This property is expressed in Lemma 5.

The key definition involved is the one of refinement with shift as defined now.

Definition 4. Given two terms $s, t$, some set $P \subseteq Q$, and some real number $x$, then $t$ refines $s$ for $P$ with shift $x$ if

$\text{Reach}(s) = \text{Reach}(t)$,

for all runs $\rho$ of $A_{\text{max}}$ over $s$ to a state $p \in P$, there is a run $\rho'$ over $t$ to state $p$ such that

$\text{weight}(\rho) \leq \text{weight}(\rho') + x$

and
The two following facts are straightforward to verify.

**Lemma 5.** Let $c$ be a context, and $s,t$ be terms such that $t$ refines $s$ for $\text{Prod}(c)$ with shift $x$, then

$$[A_{\text{max}}](c \circ s) \leq [A_{\text{max}}](c \circ t) + x \leq [A_{\text{min}}](c \circ t) + x \leq [A_{\text{min}}](c \circ s).$$

**Proof.** Let $\rho$ be an accepting run of $A_{\text{max}}$ over $c \circ s$. It can be decomposed as an accepting run $\rho_c$ over $c$ from some state $p$ and a run $\rho_s$ over $s$ to state $p$. The run $\rho_c$ is a witness that $p \in \text{Prod}(c) \cap Q_{\text{max}}$. Hence, since $t$ refines $s$ for $\text{Prod}(c)$ with shift $x$, there exists a run $\rho_t$ over $t$ to state $p$ such that $\text{weight}(\rho_s) \leq \text{weight}(\rho_t) + x$. By gluing $\rho_t$ with $\rho_c$, we obtain a new accepting run $\rho'$ of $A_{\text{max}}$ over $c \circ s$, and furthermore,

$$\text{weight}^\text{acc}(\rho) = \text{weight}^\text{acc}(\rho_c) + \text{weight}(\rho_s) \leq \text{weight}^\text{acc}(\rho_c) + \text{weight}(\rho_t) + x = \text{weight}^\text{acc}(\rho') + x.$$

Since for all $\rho$ there exists such a $\rho'$, we obtain

$$[A_{\text{max}}](c \circ s) \leq [A_{\text{max}}](c \circ t) + x.$$

The middle inequality simply comes from the key assumption $[A_{\text{max}}] \leq [A_{\text{min}}]$ in Theorem 2. The third inequality is established as the first one (it is in symmetric).

The two following facts are straightforward to verify.

**Fact 6** (reflexivity of refinement with shift). For all terms $s$, and all $P \subseteq Q$, $s$ refines $s$ for $P$ with shift 0.

**Fact 7** (transitivity of refinement with shift). If $t$ refines $s$ for $P$ with shift $x$, and $u$ refines $t$ for $P$ with shift $y$, then $u$ refines $s$ for $P$ with shift $x+y$.

The next lemma is also purely mechanical.

**Lemma 8** (refinement with shift is a congruence). Let $((P_0, R_0), \ldots, (P_{n-1}, R_{n-1}), a, (P, R)) \in \Delta_{\text{pro}}$, and for all $i = 0 \ldots n-1$, let $t_i, s_i$ be terms such that

- $\text{Reach}(t_i) = R_i$, and
- $t_i$ refines $s_i$ for $P_i$ with shift $x_i$, then $a(t_0, \ldots, t_{n-1})$ refines $a(s_0, \ldots, s_{n-1})$ for $P$ with shift $x_0 + \cdots + x_{n-1}$.

**Proof.** Let $\rho$ be a run of $A_{\text{max}}$ over $a(t_0, \ldots, t_{n-1})$ to state $p \in P$. The run $\rho$ can be decomposed into a transition $((p_0, \ldots, p_{n-1}), a, p)$ of weight $x$ at the root, and a run $\rho_i$ of $A_{\text{max}}$ over $t_i$ to $p_i$ for all $i = 0 \ldots n-1$. For all $i = 0 \ldots n-1$, $p_i \in \text{Reach}(t_i) = R_i$. Since furthermore $p \in P$ and $((P_0, R_0), \ldots, (P_{n-1}, R_{n-1}), a, (P, R)) \in \Delta_{\text{pro}}$, we obtain that $p_i \in P_i$ for all $i = 0 \ldots n-1$ (second item of the definition of $\Delta_{\text{pro}}$). Thus, since $t_i$ refines $s_i$ for $P_i$ with shift $x_i$, there exists a run $\rho'_i$ of $A_{\text{max}}$ over $t_i$ to $p_i$ such that weight($p_i$) $\leq$ weight($p'_i$) $+$ $x_i$. 

---

T. Colcombet and S. Lombardy  XX:7
We can combine all these runs $\rho'_i$ together with the transition $(p_0, \ldots, p_{n-1}, a, p)$ and obtain a new run $\rho' \in A_{\text{max}}$ over $a(t_0, \ldots, t_{n-1})$ to $p$ such that

$$\text{weight}(\rho) = \text{weight}(\rho_0) + \cdots + \text{weight}(\rho_{n-1}) + x \leq \text{weight}(\rho'_0) + x_0 + \cdots + \text{weight}(\rho'_{n-1}) + x_{n-1} + x = \text{weight}(\rho') + x_0 + \cdots + x_{n-1}.$$  

This shows half of the fact that $a(t_0, \ldots, t_{n-1})$ refines $a(s_0, \ldots, s_{n-1})$ for $P$ with shift $x_0 + \cdots + x_{n-1}$. The other half is symmetric. ▶

We aim now at proving Corollary 11 which states that all sufficiently large term is ‘shift refined’ by another one of smaller size. Beforehand, we need a pumping argument for establishing:

**Lemma 9.** Let $P \in \text{Productive}$, $R \in \text{Reachable}$ and $m$ be a context, then there exists a real number $x$ such that:

- for all runs $\rho$ of $A_{\text{max}}$ over $m$ from $p$ to $p$ with $p \in P \cap R$, $\text{weight}(\rho) \leq x$, and
- for all runs $\tau$ of $A_{\text{min}}$ over $m$ from $q$ to $q$ with $q \in P \cap R$, $x \leq \text{weight}(\tau)$.

**Proof.** Let $t$ be a term such that $\text{Reach}(t) = R$, and $c$ be a context such that $\text{Prod}(c) = P$.

**Claim:** We claim first that for all runs $\rho$ of $A_{\text{max}}$ over $m$ from $p$ to $p$ with $p \in P \cap R$ and all runs $\tau$ of $A_{\text{min}}$ over $m$ from $q$ to $q$ with $q \in P \cap R$, $\text{weight}(\rho) \leq \text{weight}(\tau)$. Indeed, otherwise, there would exist some runs $\rho, \tau$ as above such that $\text{weight}(\rho) > \text{weight}(\tau)$. I.e.

$$\text{weight}(\tau) = \text{weight}(\rho) < 0 \quad \text{(*)}$$

Consider now for all $n > 0$ the term:

$$u_n = c \circ m \circ \cdots \circ m \circ t.$$  

Let $\rho'$ be some accepting run over $c$ from $p$ (this is possible since $p \in P = \text{Prod}(c)$). Let $\tau'$ be some accepting run over $c$ from $q$ (this is possible since $q \in P = \text{Prod}(c)$). Let $\rho''$ be some run over $t$ to $p$ (this is possible since $p \in R = \text{Reach}(t)$). Let $\tau''$ be some run over $t$ to $q$ (this is possible since $q \in R = \text{Reach}(t)$).

By concatenating $\rho'$, $n$-times $\rho$, and $\rho''$, we obtain an accepting run $\rho_n$ over $u_n$ of weight $\text{weight}^{\text{acc}}(\rho_n) = \text{weight}^{\text{acc}}(\rho') + n \text{weight}(\rho) + \text{weight}(\rho'')$. Similarly, by concatenating $\tau'$, $n$-times $\tau$, and $\tau''$, we obtain an accepting run $\tau_n$ over $u_n$ of weight $\text{weight}^{\text{acc}}(\tau_n) = \text{weight}^{\text{acc}}(\tau') + n \text{weight}(\tau) + \text{weight}(\tau'')$.

Furthermore, since $[A_{\text{max}}](u_n) \leq [A_{\text{min}}](u_n)$, $\text{weight}^{\text{acc}}(\rho_n) \leq \text{weight}^{\text{acc}}(\tau_n)$. We obtain

$$0 \leq \text{weight}^{\text{acc}}(\tau_n) - \text{weight}^{\text{acc}}(\rho_n) = \text{weight}^{\text{acc}}(\tau') + n \text{weight}(\tau) + \text{weight}(\tau'') - \text{weight}^{\text{acc}}(\rho') - n \text{weight}(\rho) - \text{weight}(\rho'') = (\text{weight}^{\text{acc}}(\tau') + \text{weight}(\tau'') - \text{weight}^{\text{acc}}(\rho') - \text{weight}(\rho'') + n(\text{weight}(\tau) - \text{weight}(\rho)).$$

However, using $(*)$, this last quantity tends to $-\infty$ when $n$ tends to $\infty$. It contradicts its non-negativeness. The claim is established.

We can now establish the lemma. Let $Y$ be the set of weights $\text{weight}(\rho)$ for $\rho$ ranging over the runs of $A_{\text{max}}$ over $m$ from $p$ to $p$ with $p \in P \cap R$. Similarly, let $Z$ be the set of weights $\text{weight}(\tau)$ for $\tau$ ranging over the runs of $A_{\text{min}}$ over $m$ from $q$ to $q$ with $q \in P \cap R$.

The above claim states that for all $y \in Y$ and all $z \in Z$, $y \leq z$. This implies the existence of some real number $x$ such that for all $y \in Y$, $y \leq x$, and for all $z \in Z$, $x \leq z$ (note that proving it requires to treat the case of $Y$ and/or $Z$ being empty, and thus requires a case distinction). This is exactly the statement of the lemma. ▶
Lemma 10. There exists a computable \( k \in \mathbb{N} \) such that for all \( P_0 \in \text{Reachable} \) and all terms \( s \) of height more than \( k \), there exists effectively a term \( t \) such that \( t \) refines \( s \) for \( P \) with some shift and \( \text{size}(t) < \text{size}(s) \).

Proof. Let \( k \) be \((4|Q|)^{|Q|}\). Let us fix a context \( d \) such that \( \text{Prod}(d) = P_0 \).

Consider now a term \( s \) of height larger than \( k \) and some \( P_0 \in \text{Reachable} \). We aim at removing some piece of this term while achieving the conclusions of the lemma.

For all states \( p \in P_0 \), set \( \rho_p \) to be an optimal run of \( A \) over \( s \) to \( p \), i.e.,

- if \( p \in Q_{\text{max}} \), then for all runs \( \tau \) of \( A_{\text{max}} \) over \( s \) to \( p \), \( \text{weight}(\tau) \leq \text{weight}(\rho_p) \), and
- if \( p \in Q_{\text{min}} \), then for all runs \( \tau \) of \( A_{\text{min}} \) over \( s \) to \( p \), \( \text{weight}(\rho_p) \leq \text{weight}(\tau) \).

Since the longest branch of \( t \) has length greater than \( 2^{|Q|}2^{|Q|}Q^{|Q|} \), we can apply the pigeonhole principle to the various ways to split this branch in two, and get a factorisation of \( s \) into

\[
\begin{align*}
s &= c \circ m \circ s',
\end{align*}
\]

in which \( c \) is a context, \( m \) is a non-empty context, and \( s' \) is a term such that

- \( \text{Reach}(s') = \text{Reach}(m \circ s'); \) let \( R \) be this set;
- \( \text{Prod}(d \circ c) = \text{Prod}(d \circ c \circ m); \) let \( P \) be this set;
- for all \( p \in P_0 \), there exists a state \( q_p \in Q \) such that \( \rho_p \) is decomposed into a run \( \tau_p \) over \( s' \) to \( q_p \), a run \( \tau_p' \) over \( m \) from \( q_p \) to \( q_p \), and a run \( \tau_p'' \) over \( s' \) to \( q_p \).

Let us define now our term \( t \) as:

\[
\begin{align*}
t &= c \circ s'.
\end{align*}
\]

Since \( s = c \circ m \circ s' \), our new term \( t \) is nothing but \( s \) in which the non-empty part corresponding to \( m \) has been removed. Hence \( \text{size}(t) < \text{size}(s) \).

We shall prove now that \( t \) refines \( s \) for \( P_0 \) with shift \( x \) where \( x \) is obtained by applying Lemma 9 to \( P, R \) and \( m \).

Let \( \rho \) be a run of \( A_{\text{max}} \) over \( s \) to state \( p \) for some \( p \in P_0 \). We know that the run \( \rho_p \) as defined above is such that \( \text{weight}(\rho) \leq \text{weight}(\rho_p) \). Finally, let \( \rho' \) be the run over \( t = c \circ s' \) to \( p \) obtained by gluing \( \tau_p \) and \( \tau_p'' \) together. We have:

\[
\begin{align*}
\text{weight}(\rho) &\leq \text{weight}(\rho_p) & (\text{by optimality of } \rho_p) \\
&\leq \text{weight}(\tau_p) + \text{weight}(\tau_p') + \text{weight}(\tau_p'') & (\text{decomposition of } \rho_p) \\
&\leq \text{weight}(\tau_p) + x + \text{weight}(\tau_p'') & (\text{by choice of } x \text{ and Lemma 9}) \\
&\leq \text{weight}(\rho') + x. & (\text{definition of } \rho')
\end{align*}
\]

Hence, we have proved the first half of the definition of \( \text{‘t refines s for P_0 with shift x’}. \) The second half is symmetric. Overall, we conclude that \( t \) refines \( s \) for \( P_0 \) with shift \( x \). \( \triangleright \)

Using iteratively the above Lemma 10, as long as the height of the term is larger than \( k \), together with Fact 6 and 7, we obtain the following corollary.

Corollary 11. There exists a computable \( k \in \mathbb{N} \) such that for all \( P \in \text{Reachable} \) and all terms \( s \) there exists effectively a term \( t \) of height at most \( k \) which refines \( s \) for \( P \) with some shift.
3.4 The construction

We are now ready to construct our separating automaton $A_{\text{sep}}$. It is defined as follows:

$$A_{\text{sep}} = (Q_{\text{sep}}, A, F_{\text{sep}}, \Delta_{\text{sep}}, \text{weight}_{\text{sep}}),$$

in which the set of states is

$$Q_{\text{sep}} = \{(R, P, t) \mid R \in \text{Reachable}, \ P \in \text{Productive},$$

$$t \in \text{Terms}, \ \text{Reach}(t) = R, \ \text{height}(t) \leq k\},$$

(where $k$ is the constant from Corollary 11), the final states, together with their weight, are

$$F_{\text{sep}} = \{(R, P, t) \in Q_{\text{sep}} \mid P = F, \ R \cap F \neq \emptyset\} \quad \text{with} \quad \text{weight}_{\text{sep}}(R, F, t) = [A_{\text{max}}](t),$$

and the transition relation and the weights are defined as follows. For a letter $a$ of rank $n$, there is a transition of the form

$$\delta = ((R_0, P_0, t_0), \ldots, (R_{n-1}, P_{n-1}, t_{n-1}), a, (R, P, t)) \in \Delta_{\text{sep}} \quad \text{with} \quad \text{weight}_{\text{sep}}(\delta) = x,$$

whenever

$$= ((R_0, P_0), \ldots, (R_{n-1}, P_{n-1}), a, (R, P)) \text{ is a transition of } \Delta_{\text{pro}}.$$

$$= (t, x) = \text{sr}_P(a(t_0), \ldots, a(t_{n-1})), \text{ where } \text{sr} \text{ is a map of the following form:}$$

$$\text{sr}_P: \text{Terms} \rightarrow \text{Terms} \times \mathbb{R}$$

$$s \mapsto (t, x) \quad \text{such that } t \text{ refines } s \text{ for } P \text{ with shift } x.$$

(Such a map exists thanks to Corollary 11.)

Let us first note:

\begin{itemize}
  \item \textbf{Lemma 12.} For all $P \in \text{Productive}$ and all terms $s$, there exists exactly one run of $A_{\text{sep}}$ over $s$ to a state of the form $(R, P, t)$.
\end{itemize}

\textbf{Proof.} Indeed, we have seen in Lemma 3 that $A_{\text{sep}}$ is unambiguous on its first two components. Then the third component is computed in a bottom-up deterministic manner. Furthermore, it is easy to show by induction that on every input term there is an accepting run. $\blacksquare$

\begin{itemize}
  \item \textbf{Lemma 13.} Let $\rho$ be a run of $A_{\text{sep}}$ over $s$ to $(R, P, t)$, then $t$ refines $s$ for $P$ with shift $\text{weight}(\rho)$.
\end{itemize}

\textbf{Proof.} The proof is by induction on $\text{height}(s)$. Assume $s$ of the form $a(s_0, \ldots, s_{n-1})$. Let $\rho$ be the run of $A_{\text{sep}}$ over $s$ to $(R, P, t)$, let $\delta = ((R_0, P_0, t_0), \ldots, (R_{1}, P_1, t_1), a, (R, P, t))$ be the transition assumed by $\rho$ at the root. Let $\rho_i$ be the run $\rho$ restricted to the subterm $s_i$. By induction hypothesis, $t_i$ refines $s_i$ for $P_i$ with shift weight($\rho_i$). By Fact 7, $a(t_0, \ldots, t_{n-1})$ refines $s$ for $P$ with shift weight($\rho_0$) + $\cdots$ + weight($\rho_{n-1}$). By definition of weight$_{\text{sep}}$, $t$ refines $a(t_0, \ldots, t_{n-1})$ with shift weight$_{\text{sep}}(\delta)$. By Fact 7, we obtain that $t$ refines $s$ with shift weight($\rho_0$) + $\cdots$ + weight($\rho_{n-1}$) + weight$_{\text{sep}}(\delta) = \text{weight}(\rho)$. $\blacksquare$

We can now provide the concluding lemma of the proof of Theorem 2.

\begin{itemize}
  \item \textbf{Lemma 14.} $[A_{\text{max}}] \leq [A_{\text{sep}}] \leq [A_{\text{min}}]$.
\end{itemize}
We have established a separation result for tropical automata over trees.

Let $s$ be a term. By Lemma 12, there exists one and exactly one run $\rho_{\text{sep}}$ of $A_{\text{sep}}$ over $s$ to a state of the form $(R, F, t)$. By Lemma 13, $t$ refines $s$ for $F$ with shift weight($\rho_{\text{sep}}$).

Note that in this case $R = \text{Reach}(s) = \text{Reach}(t)$.

Two cases can occur. If $(R, F, t)$ is not final. In this case, there is no accepting run of $A_{\text{sep}}$ over $s$, and $[A_{\text{sep}}](s) = \bot$. However, $(R, F, t) \notin F_{\text{sep}}$ means $\text{Reach}(t) \cap F = \emptyset$, hence $\text{Reach}(s) \cap F = \emptyset$. Thus $[A_{\text{max}}](s) = [A_{\text{min}}](s) = \bot$. We indeed have $[A_{\text{max}}](s) \leq [A_{\text{sep}}](s) \leq [A_{\text{min}}](s)$.

Otherwise, $(R, F, t)$ is final, i.e. $R \cap F \neq \emptyset$. Assume for instance that there is some $R \cap Q_{\text{max}} \neq \emptyset$ (it would be the same for $Q_{\text{min}}$). This means that $[A_{\text{max}}](s) \neq \bot$. Since $[A_{\text{min}}] \succeq [A_{\text{max}}]$, this implies also $[A_{\text{min}}](s) \neq \bot$.

Let now $\rho$ be an accepting run of $A_{\text{max}}$ over $s$ of maximal value, and let $p$ be its root state. Since $t$ refines $s$ for $F$ with shift weight($\rho_{\text{sep}}$), and $p \in F$, there exists a run $\rho'$ over $t$ to state $p$ such that weight($\rho$) $\leq$ weight($\rho'$) + weight($\rho_{\text{sep}}$). Hence,

$$[A_{\text{max}}](s) = \text{weight}_{\text{acc}}(\rho)$$
$$= \text{weight}(\rho) + \text{weight}_{\text{max}}(p)$$
$$\leq \text{weight}(\rho') + \text{weight}_{\text{max}}(p) + \text{weight}(\rho_{\text{sep}})$$
$$\leq [A_{\text{max}}](t) + \text{weight}(\rho_{\text{sep}})$$
$$= [A_{\text{sep}}](s)$$

In a symmetrical way, we obtain:

$$[A_{\text{sep}}](s) = \text{weight}_{\text{acc}}(\rho)$$
$$= [A_{\text{max}}](t) + \text{weight}(\rho_{\text{sep}})$$
$$\leq [A_{\text{min}}](t) + \text{weight}(\rho_{\text{sep}})$$
$$\leq [A_{\text{min}}](s).$$

Hence, we have established the expected $[A_{\text{max}}](s) \leq [A_{\text{sep}}](s) \leq [A_{\text{min}}](s)$.

## 4 Conclusion

We have established a separation result for tropical automata over trees.

We did not pay attention to the complexity of our construction. In a practical implementation, an improvement can easily be made: It is not necessary to use all terms $t$ of height up to $k$ in $Q_{\text{sep}}$: it is sufficient to keep minimal ones for the shift refine relation for each $P \in \text{Productive}$. Corollary 11 gives a crude upper bound on a sufficient number of these minimal terms. It is not clear if the exact bound is significantly better.

More interestingly, our result is under the assumption that $[A_{\text{max}}] \leq [A_{\text{min}}]$. A natural variant is to invert the inequality and ask whether separation is possible when $[A_{\text{min}}] \leq [A_{\text{max}}]$. Some separation results exist in both variants (like interpolation results in logic), while some do not (separation of Büchi automata, or Lusin’s theorem). For tropical automata, the assumption $[A_{\text{min}}] \leq [A_{\text{max}}]$ would be more complicated than the one in our theorem: it can be witnessed for instance by the fact that it is not decidable anymore [9].

Another interesting question is whether similar results can hold for weights other than reals. For instance here, our proof requires for the weights of our automata to be equipped with a monoid structure, that it is commutative (otherwise weighted tree automata are not well defined), a total order (for the hypotheses of Theorem 2 to be meaningful), that the product be compatible with the order, and archimedianity (for the pumping argument in Lemma 9 to hold). The usefulness of each of these assumption could be studied. What if the
monoid is not commutative (over words)? What if the order is not total (and be, for instance a lattice)? What if the operation is not archimedian (and what does it mean in these more general cases)? And in all these situations, do we capture interesting forms of automata?

More generally, these results of separation are fascinating, and it would be interesting to understand at high level what kind of abstract arguments may explain them, or at least some of them, uniformly.
