ABSTRACT
Three-dimensional FLASH radiation-magnetohydrodynamics (radiation-MHD) modeling is carried out to study the hydrodynamics and magnetic fields in the shock-shear derived platform. Simulations indicate that fields of tens of Tesla can be generated via the Biermann battery effect due to vortices and mix in the counterpropagating shock-induced shear layer. Synthetic proton radiography simulations using MPRAD and synthetic X-ray image simulations using SPECT3D are carried out to predict the observable features in the diagnostics. Quantifying the effects of magnetic fields in inertial confinement fusion and high-energy-density plasmas represents frontier research that has far-reaching implications in basic and applied sciences.

I. INTRODUCTION
When an inertial confinement fusion (ICF) capsule implodes, the material turns into dense plasmas and recent simulations have shown that such plasmas tend to be unstable and turbulence can develop.1 Even though it is debated whether turbulence is damped by the viscosity in the hot spot, the shocked interfaces as well as the interface between the shell and the hot spot can have very different dynamics and can indeed be unstable.2–7 It is believed that turbulence and the associated mixing process can be crucial for understanding ICF.

The Biermann battery effect8 is known to generate seed magnetic fields in laser driven plasma flows and has been studied extensively in high-energy-density (HED) laser-driven experiments,9–16 but the strength and importance of these fields in the close to or higher than solid density plasmas such as an ICF implosion are not well known. Three-dimensional extended-magnetohydrodynamic (extended-MHD) simulations of the stagnation phase of ICF including the Biermann battery term,8 Nernst term,17 and anisotropic heat conduction in the magnetic field indicate that self-generated magnetic fields can reach over $10^4$ Tesla and can affect the electron heat flow.18 The simulations with premagnetization for ICF implosions show the significance of Lorentz force and $\gamma$-particle trapping.19 In low density laser driven plasmas, the magnetic field can be amplified by turbulence and measured using temporal diagnostics by the B-dot probe20 and spatial diagnostics by proton radiography.21 The magnetic frequency spectrum in supersonic plasma turbulence has been measured in a recent experiment22 on the Vulcan laser. However, in those experiments...
the magnetic field is not high enough to change the dynamics of the hydrodynamical flow.

In this work, we use the shock-shear platform\textsuperscript{23,24} developed at the Los Alamos National Laboratory (LANL) to quantify the dynamics of magnetic fields in HED plasmas with instabilities and turbulence. The shock compression can achieve a regime where the density is around 1 g/cc. The targets with large density can diffuse the proton beam and affect the interpretation of the proton image,\textsuperscript{25} but the simulations for the synthetic proton image including the stopping power and Coulomb scattering show that the deflection of the proton beam by magnetic fields is still detectable. Further improvements are still needed to make the fields high enough to change the dynamics of the small-scale evolution of vortices like those in a turbulent cascade and affect our understanding of turbulence.

The shock-shear platform,\textsuperscript{23,24} as a platform to isolatedly study the shear-induced instabilities and turbulence production under HED conditions, i.e., pressure larger than 1 Mbar, has been used to investigate the turbulent mixing\textsuperscript{26,27} at material interfaces when subject to multiple shocks and reshears or high-speed shear.\textsuperscript{28,29} The experiments\textsuperscript{30–33} using the shock-shear platform have been carried out on the OMEGA Laser Facility and National Ignition Facility (NIF). These experiments provide quantitative measurements to assist in validation efforts\textsuperscript{34–36} for mix models, such as the Besnard-Harlow-Rauenzahn (BHR) model.\textsuperscript{37,38} The experimental data and the validation efforts constrain models relevant to integrated HED experiments such as ICF or astrophysical problems. In the shock-shear targets, the Biermann battery ($\nabla n_e \times \nabla T_e$) terms\textsuperscript{39} can generate and sustain strong magnetic fields in the vortices due to the misalignment of the density gradient and temperature gradient caused by electron heat conduction. However, the magnetic fields in the shock-shear targets have not been quantified in simulations or experiments.

In this work, we use the radiation-MHD code FLASH\textsuperscript{39,40} to model the evolution of the shock-shear system on OMEGA.\textsuperscript{41} The experiment simulated in this paper uses 8 beams each with 500 J energy laser ablation in 1 ns on each side to drive strong adjacent contour-propagating shocks. Kelvin-Helmholtz instability laterally spreads across a thin layer of magnesium, copper, or plastic placed at the interface. The layer is cut with slots to seed the initial density perturbation, which can generate vortices during the evolution of the shock and shear. The temperature of the materials reaches tens of electron-volts, and simulations predict that the Mach number of the postshock flows in the experiment is around 2 on each side of the shear layer. The magnetic field is generated by the Biermann battery term\textsuperscript{42} and dissipated by the resistive term. The X-ray image\textsuperscript{42–44} and the proton radiograph\textsuperscript{45} are predicted and will be compared to the experimental data in a later paper.

This paper is organized as follows. Section II describes simulation methods and the configuration of the target system. In Sec. III, we show the results for hydrodynamics and MHD evolution from FLASH, the synthetic X-ray image using SPECT3D, and the synthetic proton radiography using MPRAD. The conclusions and discussions are given in Sec. IV.

II. SIMULATION METHODS AND CONFIGURATION

The FLASH code\textsuperscript{39,40,41} is used to carry out the detailed physics simulations of our laser experiments to study the dynamics of the shock-shear system. FLASH is a publicly available, multiphysics, highly scalable parallel, finite-volume Eulerian code and framework whose capabilities include adaptive mesh refinement (AMR), multiple hydrodynamic and MHD solvers,\textsuperscript{46–50} implicit solvers for diffusion using the HYPRE library,\textsuperscript{50} and laser energy deposition. FLASH is capable of using the multi-temperature equation of states and multi-group opacities. To simulate laser-driven High-Energy-Density-Physics (HEDP) experiments, a 3 T treatment, i.e., $T_{ion} \neq T_{ele} \neq T_{abs}$, is usually adopted. The equations which FLASH solves to describe the evolution of the 3 T magnetized plasma are

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (1)$$

$$\frac{\partial \rho \mathbf{v}}{\partial t} + \nabla \left( \rho \mathbf{v} \mathbf{v} - \frac{1}{4\pi} \mathbf{B} \mathbf{B} \right) + \nabla P_{tot} = 0, \quad (2)$$

$$\frac{\partial \rho E_{tot}}{\partial t} + \nabla \cdot (\rho \mathbf{v} E_{tot} + P_{tot} - \frac{1}{4\pi} \mathbf{B} (\mathbf{v} \cdot \mathbf{B})) = \nabla \cdot \mathbf{q} + S, \quad (3)$$

$$\frac{\partial \mathbf{B}}{\partial t} + \nabla \cdot (\mathbf{v} \mathbf{B} - \mathbf{B} \mathbf{v}) = -\nabla \cdot \left( \eta \nabla \mathbf{v} + \mathbf{B} \times \left( \frac{c}{\epsilon} \nabla \mathbf{v} + \frac{c}{\epsilon} \nabla \mathbf{P}_{ele} n_e \right) \right), \quad (4)$$

where the total pressure is given by $P_{tot} = P_{ion} + P_{ele} + P_{rad} + (1/8\pi)r^2$ and the total specific energy $E_{tot} = c_{ion} + c_{ele} + c_{rad} + (1/8\pi)r^2 B^2 + \frac{1}{2} \mathbf{v} \cdot \mathbf{v}$. The total heat flux $\mathbf{q}$ is the summation of electron heat flux $\mathbf{q}_e = -\kappa \nabla T_{ele}$ and radiation flux $\mathbf{q}_r$, where $\kappa$ is the Spitzer electron heat conductivity.\textsuperscript{51,52} The flux-limit used for electron thermal conduction is set to be 6% of the free streaming flux $\mathbf{q}_S = n_e k_B T_e \sqrt{k_B T_e}/m_e$.

The first term on the R.H.S of Eq. (4) contains the Spitzer magnetic resistivity $\eta_B$.\textsuperscript{51,52} The second term on the R.H.S of Eq. (4) is the Biermann battery term, which generates the magnetic field even if there is no seed magnetic field initially. The plasma has zero initial magnetic field in the simulations. Because plasma beta $\beta$ is much larger than unity, the Hall term is neglectable and not included in the simulations. The Biermann battery term is turned off in the cells adjacent to the shock detected numerically.\textsuperscript{53} The magnetic field generation near the shock is not calculated because of the convergence problem\textsuperscript{54} for calculating the Biermann battery term on the Eulerian grid. The convergence problem might be resolved on a Lagrangian grid. On the other hand, the shock in this work is highly collisional and with a small thickness compared to the spatial resolution of proton radiography, thus the scale of the magnetic field near the shock is too small to be detectable. The energy equations for the three components are

$$\frac{\partial}{\partial t} (\rho c_{ion}) + \nabla \cdot (\rho c_{ion} \mathbf{v}) + P_{ion} \nabla \cdot \mathbf{v} = \rho \frac{c_{ele}}{\epsilon_{ei}} (T_{ele} - T_{ion}), \quad (5)$$

$$\frac{\partial}{\partial t} (\rho c_{ele}) + \nabla \cdot (\rho c_{ele} \mathbf{v}) + P_{ele} \nabla \cdot \mathbf{v}$$

$$= \rho \frac{c_{ele}}{\epsilon_{ei}} (T_{ion} - T_{ele}) - \nabla \cdot \mathbf{q}_{ele} + Q_{abs} - Q_{emis} + Q_{dis} + Q_{abs}, \quad (6)$$

$$\frac{\partial}{\partial t} (\rho c_{rad}) + \nabla \cdot (\rho c_{rad} \mathbf{v}) + P_{rad} \nabla \cdot \mathbf{v} = \nabla \cdot \mathbf{q}_{rad} - Q_{abs} + Q_{emis}, \quad (7)$$
where $c_{e,\text{ke}}$ is the electron specific heat and $\tau_{\text{ie}}$ is the ion-electron Coulomb collision time. $Q_{\text{abs}}$ (absorption) and $Q_{\text{emis}}$ (emission) describe the energy transfer between the electron and the radiation, which is modeled using the multigroup flux-limited radiation diffusion. The laser absorption term $Q_{\text{abs}}$ is computed using ray-tracing in the geometric optics approximation via the inverse-Bremstrahlung process. $Q_{\text{abs}}$ is the rate of electron energy increase due to Ohmic heating. The auxiliary equations Eqns. (5)–(7) are advanced in time such that the distribution of energy change due to the work and the total shock-heating is based on the pressure ratio of the components, which is a method implemented in FLASH inspired by the radiation-hydrodynamics code RAGE. We use the equation of state and opacity table from PROPAEOS57,58 for modeling all the material properties in our target system.

We initialize the FLASH simulation using the geometry and parameters of targets used for OMEGA experiments. The target system is composed of the shock tube, the gold cone for minimizing stray laser light, the foam filling the shock tube, and a plastic cap covering the end of the tube, as shown in Fig. 1. As shown in Fig. 1(c), a window is opened in the middle of the tube and along the path of the proton beam to make the proton beam less diffusive, i.e., less energy lost and scattering. However, the opened window can make the plasma squat outwardly. We use the foam with density 62 mg/cc, and the foam is divided by a layer with slanted or nonslanted slots, as shown in Figs. 1(e) and 1(f). The end cap is 1 g/cc plastic. The shape of the slots, the material, and the thickness of the layer, and the material of the wall are listed in Table 1. Some targets are built with a pepper-pot screen (PPS), as shown in Fig. 1(b). The PPS is used for a narrow view of the proton deflection signal in proton radiography, reducing the signal contamination from off-center line-of-sight. The 200 $\mu$m diameter hole in the middle allows proton beams to go through the central part of the target. Other holes are used as references to register the position of protons. The PPS is a 40 $\mu$m thick tantalum foil.

In the initialization, the pressure of all the solid regions is $5 \times 10^9$ bar ($= 5 \times 10^6$ erg/cm$^3$), and the temperature is calculated self-consistently from the equation of state table. Using the same pressure instead of the same temperature among all the solid regions can prevent one solid region from expanding into another solid region and launching artificial shocks before the high-energy-density conditions are reached. Under HED conditions, the pressure is larger than $10^9$ bar ($= 10^{15}$ erg/cm$^3$); thus, the initial pressure is low enough to have a negligible effect on the simulations. The vacuum region is initially filled with $10^{-6}$ g/cc helium to avoid numerical problems in hydrodynamics or MHD solvers. The density is low enough that the effect of helium on the simulations is negligible.

A 3D cartesian grid with $(240 \times 240 \times 464)$ zones is used to resolve a $(1440 \mu$m $\times 1440 \mu$m $\times 2784 \mu$m) domain, corresponding to 6 $\mu$m per cell width. Using AMR, each zone is adaptively refined to one leaf level, i.e., a resolution of 3 to 6. The density is low enough that the turbulence dissipation scale with the current computing capability and neither do we use Reynolds-averaging Navier-Stokes (RANS) models such as the BHR model to resolve the small scale dissipation process of the fluid, FLASH is still a suitable tool for designing these experiments because the fabricated layers have low surface roughness.

To model the laser driven energy deposition, we use the spatial and temporal specifications of each of the 16 OMEGA driver beams. Ray tracing by solving the geometric optics and the inverse bremsstrahlung absorption is used. The 16 driver beams are turned on and turned off simultaneously with a 1 ns pulse duration and 8 beams on each side of the target. Each delivers 500 J of energy on a target. The radius of each beam is 283 $\mu$m and the intensity distribution we use is Gaussian.

For convention, $t = 0$ is the time for laser turn on. The axis of the shock tube is the $z$ axis. The layer dividing the foam is in the $y - z$ plane, i.e., the plane with $x = 0$ everywhere. The center of the target is at $x = y = z = 0$. The $x$ axis extends through the window.

The primary diagnostic for a temporally and spatially resolved profile of the density and shock propagation in the experiments is the point projection X-ray radiography with a vanadium backlighter at $23 \times$ magnification. The backlighter source emits 5180 eV and 5205 eV helium like lines. The images are recorded on the X-ray framing camera (XRFC),42–44 We use SPECT3D51,52 to generate the synthetic ray-tracing X-ray image. The line of sight of XRFC is along the $y$ axis, which captures the distortion of the layer.

Proton radiography, using $^{3}$He (14.7 MeV) protons from fusion, measures magnetic fields. The temporal resolution of the proton radiograph is typically $\sim 150$ ps and the spatial resolution is typically $\sim 45$ $\mu$m. The diffusion of the proton beam caused by Coulomb scattering53,64 and stopping power54–56 is significant for the targets we use. We use Monte Carlo code MPSRAD25 to model the synthetic proton radiography, including the Lorentz force and the effects from Coulomb scattering and stopping power. The proton source stands at $(0.75 \text{ cm}, 0, 0)$, while the image plate CR39 is located 27 cm from the center on the other side. The line of sight of the proton radiography is perpendicular to the line of sight of the X-ray image. The energy distribution of the proton source we use in the simulation is a Gaussian distribution with FWHM $= 0.25$ MeV centered at 14.7 MeV.

### III. Simulation Results

We show the results from FLASH simulations and synthetic radiography to study the evolution and dynamics of the flows in the shock-shear targets in Figs. 2–4. In the synthetic radiographs, the spatial scales of the synthetic radiographs are divided by the magnification to align with the scales on the target system. The target we use in this work is different from previous shock-shear experiments28,30,34,35 mainly in two aspects: (1) cut slots in the layer for seeding density perturbation and (2) opened window on the wall for reducing the diffusion of proton beams.

#### A. Hydrodynamics

We show the evolution of density, electron temperature, and X-ray flux in the first three rows in Figs. 2–4. The gold plugs hold back the shock at one end of each half-cylinder of foam. Two shocks of roughly the same strength in the same material propagate from opposite directions toward the center of the tube. The layer placed in the middle between the two regions collimates the shocked flows and introduces a length scale through its thickness, which will influence the dominant modes of the resulting shear instability. The cut slots in the layer introduce alternating density gradients and cause magnetic field generation by the Biermann battery term, which is discussed in Sec. III C. Because the layer does not fully collimate the shocks, oblique
TABLE I. The parameters and the maximum values of magnetic field and electron temperature for the three different targets/runs we use. $T_e$ and $B$ are calculated by averaging over a $(200 \mu m)^2$ around the center of the target in the $x-z$ plane. PPS stands for the pepper-pot screen.

FIG. 2. Spatial distribution of different quantities at different times. The size of all plots is 1200 μm × 1200 μm. From first to fourth rows are: density at the $y = 0$ plane, electron temperature at the $y = 0$ plane, X-ray flux normalized by the purely transparent flux, and magnetic field $B_y$ in kGauss at $y = 0$ plane (positive for into the plane). The plots in the second and the fourth rows are overlaid with magenta contours for the density of the wall material equal to 0.5 g/cc. From fifth to the last rows are proton images for four different cases as labeled.
FIG. 3. Same as Fig. 2 but for run B.
FIG. 4. Same as Fig. 2 but for runC.
shocks are launched into the opposite volumes of the tube. The shock front near the end of the tube travels further transversely. It takes roughly 8.5 ns for the shocks to cross and create the pressure-balanced shear mixing region. The pressure in the two regions is roughly equal and the shocked material is the same on each side of the mixing layer, so that the mixing region does not experience a net translation away from the center of the shock tube. After 8.5 ns, the oblique shock on either end of the tube gradually crosses the primary shock from the other direction. An oblique region of high density is developed by the reverse shock.

The ideally constructed target should be symmetric about a rotation of $180^\circ$. However, the different effective laser intensities on two ends of the target due to different laser incident angles cause the two shocks to move at slightly different speeds. The shock from the right side moves slightly faster as shown in the first rows in Figs. 2–4. This asymmetry does not affect the overall picture of the hydrodynamical and magnetic field evolution, but the asymmetry of the density distribution can affect the proton radiography, which is discussed in Sec. III D.

Because of the opened window on the wall, there are plasma plumes traveling outside the window. As shown in Fig. 5, the overall picture of hydrodynamical evolution is still similar to previous shock-shear experiments without a window, although the plasma plume carries mass and energy away from the tube. At later times, the shock can penetrate through the wall. This results in plumes outside the wall, which can then interact with the plume from the window.

### B. X-ray images

The transmitted X-ray flux is shown in the third rows in Figs. 2–4. In the X-ray flux, the location and the shape of the shock front is consistent with the density distribution and can be easily identified. The shocks in the wall can also be seen in the X-ray image. The plume launched from the wall or the window has low density and is not visible in the X-ray flux. The layer has high density and low X-ray transmission, leading to the low flux on the X-ray image. For runA and runB, where the layer material is magnesium and copper, respectively, the contrast of X-ray flux between the layer and the foam is high, while for runC where the layer material is CH, the X-ray contrast is low.

### C. Magnetic fields

When the shock from one end of the tube passes, the temperature is high near the center of the half-cylinder as shown in the second rows in Figs. 2–4. A cold region is left behind the shock. The temperature gradient near the layer is perpendicular to the layer and pointing toward the shocked region, due to electron heat conduction. The density gradient is alternating, caused by the cut slots on the layer. Thus, the Biermann battery term generates the alternating magnetic field in the $y$ direction, as shown in Fig. 6(a). However, the cold region left behind the shock has low electron temperature and thus high resistivity. The magnetic fields behind the shock diffuse very quickly. In the end, the only significant field left near the center of the tube is in

![Image of magnetic field generation by Biermann battery term](image)

**FIG. 6.** Schematics of the magnetic field generation by Biermann battery term ($\nabla n_e \times \nabla T_e$). (a) Near the layer, the temperature gradient is perpendicular to the layer due to thermal conduction, the density gradient is alternating and along the layer due to the cut slots on the layer, so that the Biermann generated field is alternating into and out of the plane. (b) Outside the window, the density gradient points to the dense part of the plume, the temperature gradient along the outflow direction is small due to conduction, but the temperature gradient perpendicular to the outflow direction survives due to continuous launching of the plume from the shock tube; thus the field is into the plane on the right side and out of the plane on the left side.
The magnetic field in the plume traveling outside the window is generated in a similar way to the magnetic field generated in the ablation plume of a laser interaction with a solid target.\cite{9,10,12,13} The plume is continuously launched by the flow inside the shock tube and expands in all directions, with the density gradient to point toward the dense part of the plume, as shown in Fig. 6(b). The temperature gradient along the outflow direction is reduced due to electron thermal conduction, but the temperature gradient perpendicular to the outflow direction survives due to continuous launching of the plume from the shock tube. Thus, the magnetic field generated by the Biermann battery term is into the plane on the right side and out of the plane on the left side in Fig. 6(b).

The magnetic field evolution is shown in the fourth rows in Figs. 2–4. In the center of the tube, a field pointing in \(-y\) direction dominates. Outside the window, the field pointing in \(+y\) direction survives, while the field pointing in \(-y\) direction diffuses quickly due to low temperature and high resistivity. The total magnetic flux in the \(y = 0\) plane is conserved and vanishes. We are interested in the magnetic field near the center of the tube, which can potentially affect the mix. The magnetic field outside the window plays a role in the proton radiography as discussed in Sec. III D, but we are not interested in its dynamical importance because it is far away from the mix region.

As shown in Fig. 5, the magnetic field near the center of the tube is similar between the runs with and without the window.

D. Proton radiography

We use the MPRAD code\cite{25} to simulate the proton image by taking the output data from 3D FLASH simulations. In the simulations, we use a typical size 45 \(\mu\)m for the proton source. We find that the features of the proton images are most prominent in 14.3 MeV to 14.5 MeV band, i.e., protons losing between 0.2 MeV and 0.4 MeV of kinetic energy. We compare the proton images with/without field, and with/without pepper pot screen (PPS) in the fifth to the last rows in Figs. 2–4. To quantify the asymmetry of the proton image, the averaged horizontal proton position in the blob at the center of the proton image is plotted in Fig. 7. The ideally constructed target should be symmetric about a rotation of 180\(^\circ\) and the proton image should also be symmetric in the absence of magnetic field. The asymmetry of the proton image about the vertical axis can be interpreted as the existence of magnetic field.

However, in the no PPS case, i.e., the fifth rows in Figs. 2–4, the blob in the middle of the image can be slightly asymmetric even without magnetic field. This asymmetry is not as large as the asymmetry in the images where there is field but no PPS, i.e., the six rows, which means that the proton deflection by magnetic field causes more asymmetry than by the density asymmetry due to the fact that the shock from the right side in Figs. 2–4, moves slightly faster. This slight difference is caused by the different effective laser intensities on two ends of the target due to different laser incident angles. In the simulations in this work, we do not take into account the unevenness of the foam and the power imbalance on two ends of the tube, which can potentially cause more asymmetry on the proton image than what we show in this work.

One advantage of using PPS is that the viewing of the surrounding holes is through the regions without the field and the viewing of the hole in the middle is only through the region with magnetic field, so that the net deflection caused by the magnetic field can be determined without another control shot using the same target. With PPS, the asymmetry in the no field case, i.e., the seventh rows in Figs. 2–4, is significantly less than the without field and without the PPS case, i.e., the fifth rows. The PPS is very efficient in reducing the asymmetry of the proton image caused by the intensity imbalance on two ends and the unevenness of the foam. As shown in Fig. 7(b), the asymmetry caused by the proton deflection is significantly larger than that caused by the nonuniform density. The blob has a positive net shift at early time, because of the field pointing in \(+y\) direction in the plume outside.
the window. At about 8.5 ns, the proton deflection caused by the field pointing in +y direction in the plume outside the window and by the field in near the center of the tube pointing in −y direction cancels, resulting in zero net shift of the blob on the proton image. At a late time \( t > 10 \) ns, the field pointing in +y direction moves away from the \( z = 0 \) plane, but the field near the center of the tube has no net advection, and the net shift of the blob is negative. The shift value on the image plate divided by the magnification can reach 50–70 \( \mu \text{m} \). The difference between the early time shift and late time shift can reach 70–90 \( \mu \text{m} \). The prediction for the net shift of the blob will be compared to the experimental data to validate the magnetic field model in FLASH.

IV. CONCLUSIONS AND DISCUSSION

We carried out the radiation-MHD simulations and predicted the X-ray and proton images by synthetic radiographs. The hydrodynamical evolution can be measured using XRFC and compared with the simulation results. The predicted proton radiography shows the direction and the amount of the shift of the proton beam going through the window and/or PPS. Although the target can diffuse the advection, and the net shift of the blob is negative. The shift value on \( z \) direction moves away from \( y \) direction cancels, the two-dimensional fields in the plume pointing in \( x \) direction and the amount of the shift of the proton beam going through the window. At about 8

| Plasma property                  | Formula                      | Value at \( r = 0 \) |
|----------------------------------|------------------------------|---------------------|
| Electron density \( n_e (\text{cm}^{-3}) \) | \[ \cdots \]                  | \( 5.6 \times 10^{22} \) |
| Mass density \( \rho (\text{g/cm}^3) \)     | \[ \cdots \]                  | 0.36                |
| Electron temperature \( T_e (\text{eV}) \) | \[ \cdots \]                  | 25                  |
| Ion temperature \( T_i (\text{eV}) \)     | \[ \cdots \]                  | 25                  |
| Magnetic field \( B \) (gauss)         | \[ \cdots \]                  | 1.6 \times 10^5     |
| Average ionization \( Z \)            | \[ \cdots \]                  | 1.9                 |
| Average atomic weight \( A \)         | \[ \cdots \]                  | 7.3                 |
| Flow speed \( u \) (cm/s)             | \[ \cdots \]                  | \( 7 \times 10^6 \)  |
| Sound speed \( c_s \) (cm/s)          | \[ \frac{9.8 \times 10^5 [Z T_e + 1.67 T_i]^{1/2}}{A^{1/2}} \] | \( 3.4 \times 10^6 \) |
| Mach number \( M \)                  | \[ \frac{u}{c_s} \]            | 2                   |
| Coulomb logarithm \( \ln \Lambda \)   | \[ \min(23.5 + \ln (T_e^{1/5}/n_e^{0.5}/Z), 25.3 + \ln (T_i/n_e^{1/5})) \] | 1.4                 |
| Hall parameter \( \chi \)            | \[ \frac{6.1 \times 10^{12} T_e^{3/2} B}{Z n_e \ln \Lambda} \] | \( 8 \times 10^{-4} \) |
| Plasma \( \beta \)                   | \[ \frac{2.4 \times 10^{-12}}{A^{1/2} Z n_e (T_e + T_i)/Z} \] | 5 \times 10^3        |
| Péclet number \( Pe \)               | \[ \frac{\kappa_e}{3 n_e k_B} \left( \frac{\kappa_e}{3 n_e k_B} = 5.5 \times 10^{21} \right) \] | \( 8.3 \times 10^3 \) |
| Magnetic Reynolds number \( Rm \)    | \[ \frac{u L}{\eta} \left( \frac{0.33 Z + 0.18}{T_e^{3/2}} \right) \] | 47                  |
| Reynolds number \( Re \)             | \[ \frac{u L}{\nu} \left( \frac{T_i^{1/2}}{A^{1/2} Z n_e \ln \Lambda} \right) \] | \( 8.6 \times 10^6 \) |

TABLE II. Simulated plasma properties for runA. All quantities are in cgs units except temperature, which is expressed in eV. The length scale, \( L \) is approximately the diameter of the tube (≈500 \( \mu \text{m} \)). The \( n_w, \rho, T_e, \) and \( T_i \) are calculated by averaging over a \( (200^2 \mu \text{m})^2 \) square around the center of the target in the \( x−z \) plane, at \( t = 10 \) ns. The flow speed is \( u = 7 \times 10^3 \) cm/s for each counter propagating flow.
advection term. The plasma beta $\beta$ is then proportional to $n_i T_i / (T_e / L_n)^2 \propto n_i u^2 / L^2 T_e$. If we keep the size of the target and the laser power, $n_i u^2$ and $L$ are roughly constants, and then $\beta \propto 1/T_e$. Thus, increasing $T_e$ can reduce $\beta$ and make the Lorentz force more important. The Hall parameter $\gamma$ is proportional to $B^2 / n_i$ and the magnetic Reynolds number $Rm$ is proportional to $T_e^{3/2}$. Both $\gamma$ and $Rm$ increase with temperature. For low $Rm$ and low magnetic Prandtl number $Pr_m$, i.e., $Pr_m = Rm / Re \ll 1$, the power spectrum of the kinetic energy $E(k)$ and the power spectrum of the magnetic energy $M(k)$ are related by $M(k) \propto k^{-2} E(k)$, and $M(k)$ is always softer than $E(k)$, and the magnetic field remains dynamically unimportant even in small scales.\textsuperscript{17,21,22} High $Rm$ is favorable for the amplification of magnetic fields and a hard power law for the magnetic energy spectrum.\textsuperscript{12,17,23} One way to achieve a higher temperature is to lower the density of the foam. However, making a low density foam in the target is challenging for target fabrication. It causes the unevenness in the foam, leads to the unevenness of the proton image, and makes it difficult to interpret the experimental data from proton radiography. In a low density foam, the flow may move too fast so that the time window for diagnostics is narrow.

Some experiments\textsuperscript{1} and theories\textsuperscript{15,26,27,66} show that around 10 eV, the value of electrical resistivity [electrical resistivity $\eta$ is related to magnetic resistivity $\eta_m$ by $\eta_m = (e^2/4\pi\eta)$] is different from the Spitzer resistivity. However, the electrical resistivity with temperature and density dependency under the condition of our experimental design is not well constrained. If the modeling in this work is correct in terms of electrical resistivity, then this would indicate that the magnetic field may not be dynamically important. However, if the electrical resistivity is significantly lower than the Spitzer resistivity that we use in this work, then the simulations in this work underestimate the magnetic fields, and the mix model could potentially cover up the magnetic field effects by the choice of the initial input conditions for the model. In the future development of the simulations, the implementation of the implicit method for the magnetic diffusion equation is desirable for the case of large resistivity where a fully explicit method requires a small time step.
