2Post Graduate, Department of Ophthalmology, Sri Ramachandra University.

ABSTRACT
To study the association between various types of Diabetic Macular Oedema (DME) with systemic risk factors namely hypertension, chronic renal disease and Ischaemic Heart Disease (IHD) in South Indian population.

MATERIAL AND METHODS
The study was done on 96 eyes of 50 patients. Emphasis was placed on the findings of Fundus Fluorescein Angiography (FFA) to decide about the therapeutic modality.

RESULTS
32 patients were above 50 years and 18 patients were below 50. Disease affects both eyes, although asymmetrically. In our study, 92% patients had bilateral involvement. None of the diabetic patients associated with hypertension (6 eyes of 3 patients) had DME. All diabetic patients who had chronic renal disease (100%) had either diffuse or mixed type of DME; 85% of patients having history of IHD had ischaemic maculopathy.

CONCLUSION
Ischaemic maculopathy has no treatment as such, but can definitely be considered as a warning sign for future life-threatening ischaemic cardiac events due to its strong association (85%) and hence necessary steps of prevention should be taken with help of physicians.

KEYWORDS
Ischaemic Maculopathy, Fundus Fluorescein Angiography, Ischaemic Heart Disease, Hypertension.

INTRODUCTION
Diabetes mellitus is a disorder of carbohydrate metabolism characterized primarily by hyperglycaemia and glycosuria with secondary anomalies of metabolism of proteins and fats.1 Diabetic retinopathy is a microangiopathy affecting precapillary arterioles and post-capillary venules.2 The most common cause of visual impairment in diabetic retinopathy is macular oedema.3 This is due to breakdown of blood retinal barrier. The sites of leakage are microaneurysms, intraretinal microvascular abnormalities and dilated retinal capillaries.4 Clinically significant macular oedema was not found in younger onset persons with less than 5 years diabetes. In contrast, it is present in older onset persons with first few years of diabetes. When non-proliferative diabetic retinopathy is present, older patients have macular oedema more frequently than younger onset persons. When proliferative diabetic retinopathy is present, the prevalence of maculopathy is same in IDDM and NIDDM. Macular oedema is a more common NIDDM. When young individuals have macular oedema, it is usually associated with Proliferative Diabetic Retinopathy.

Age
Diabetic children are less prone to retinopathy. Risk factors during puberty due to hormonal and metabolic changes.

Metabolic Control
Positive correlation occurs between poor metabolic control and severity of retinopathy. Worsening of retinopathy can occur following rapid control of blood glucose with appearance of cotton wool spots and IRMA.5

Clinically Significant Macula Oedema
• Retinal oedema within 500 microns of the center of the fovea.
• Hard exudates within 500 micron of the fovea, if associated with adjacent retinal thickening.
• Retinal oedema that is one disc area or larger, any part of which is within one disc diameter of the center of fovea.5
Pathological Changes in Maculopathy

- Microaneurysms: Microaneurysms are first ophthalmoscopically detectable sign of maculopathy results from progression of capillary disease. It tends to occur first along the temporal raphe predominantly on the cellular side of the capillary bed. The formation of microaneurysms reflects the disappearance of the intramural pericytes. The distribution of the microaneurysms ranges from the patchy geographical distribution in early maculopathy to scattering throughout the posterior retina in advanced maculopathy.

- Exudates: Following the development of the ischaemic foci, deep circumscribed hard yellow exudates developed at the macula. Because the outer plexiform layer at the macula has a large potential interstitial space between cells, the earliest exudative material is located in this region. The exudates distort the normal surrounding cells of the retina. The surrounding cellular elements of the outer plexiform layer undergo secondary degeneration to produce necrotic foci, which give a Swiss cheese appearance to the histological section of the posterior retina.

- Macular oedema: Macular oedema is a distinct process where serous fluid accumulate within the retinal layers. The fluid accumulates first in the microcystic spaces in the retinal layer and then the cystic spaces containing serous fluid. These eventually lead to major decrease in visual acuity. Oedema of fovea due to loss of the perifoveal capillary bed is commonly seen in juvenile onset diabetes. It may also occur following photocoagulation treatment.

- Macular Ischaemia: Assessing the blood supply to macula is important, because inadequate blood supply may itself cause a decrease in visual acuity. Macular ischaemia may be divided into three types.

- Focal capillary dropout.

- Enlargement of the normal FAZ secondary to occlusion of the perifoveal capillaries.

- Non-perfusion of large areas of the macula occurs with occlusion of precapillary arterioles or larger retinal arterioles.

- Preretinal and vitreoretinal changes: It is due to proliferation and shrinkage of fibrous, glial and fibrovascular tissues.

Vulnerability of Macula is Due to

- Abundance of Henle’s fibres, which are hydrophilic.

- Relative avascularity, which limits fluid absorption.

- Thin basal lamina which offers little protection against any biochemical effects.

Types of Macula Oedema

1. Focal macular oedema: Localized area of retinal thickening results from microaneurysms and IRMA. They are delineated from normal retina by complete or partial ring of exudates. Subretinal deposits occurs in severe cases.

2. Diffuse macular Oedema: Occurs from dilated vessels at posterior pole. Patent capillaries dilate and leak to cause diffuse oedema. It is not usually associated with hard exudates. Bilateral symmetry is a common feature.

Clinical Evaluation of Macula

Symptoms include defective vision positive ascotamas, metamorphopsia, micropsia and vertical diplopia due to tractional detachment of macula.

AIM

To study the association between various types of Diabetic Macular Oedema (DME) with systemic risk factors namely hypertension, chronic renal disease and Ischaemic Heart Disease (IHD) in South Indian population.

MATERIAL AND METHODS

- The study was done on 96 eyes of 50 patients. Emphasis was placed on the findings of Fundus Fluorescein Angiography (FFA) to decide about the therapeutic modality. Best corrected visual acuity was noted using Snellen chart. Intraocular pressure was measured using Goldmann’s applanation tonometry. Evaluation of anterior segment was done using slit lamp. Fundus examination was done using slit lamp biomicroscopy with +78D lens supplemented by indirect ophthalmoscope. Status of angle and vitreous cavity was assessed by Goldmann three mirror gonio lens. Fundus photograph and FFA was done using Zeiss fundus photo camera. Laser photocoagulation was performed by Zeiss double frequency Nd:YAG laser. Blood pressure was measured using sphygmomanometer. Renal function tests, baseline ECG/2D echo was done wherever necessary. Physician/Cardiologist’s opinion was taken wherever necessary. Patients with diabetes either referred or detected at Sri Ramachandra Hospital were taken into study. Associated systemic factors like hypertension, renal disease and ischaemic heart disease were recorded. FFA was done using 5 mL of 10% sodium fluorescein. The dye is injected intravenously into the antecubital vein with the patient seated in front of the fundus camera. After FFA, patients were classified accordingly.

- Focal DME.

- Diffuse DME.

- Ischaemic DME.

RESULTS

- 32 patients were above 50 years and 18 patients were below 50 years.

- Disease affects both eyes, although asymmetrically. In our study, 92 percent of patients had bilateral involvement.

- None of the diabetic patients associated with hypertension (6 eyes of 3 patients) had DME.
All diabetic patients who had chronic renal disease (100%) had either diffuse or mixed type of DME.

85% of patients having history of IHD had ischaemic maculopathy.

**ANALYSIS AND DISCUSSION**

**Lesions in FFA:**

1. **Focal lesions:** The hard exudates have microaneurysms at their centre. On angiogram microaneurysms are seen as hyperfluorescent spots. Some may not perfuse or perfuse slowly. They appear as dark silhouettes on angiogram. Leakage of microaneurysms can occur. Hard exudates and haemorrhages produce blocked fluorescein.

2. **Diffuse lesions:** Angiography shows dilatation of capillaries and leak in the early arteriovenous phase. Cystoid pattern can occur. The dye persists for a long time.

3. **Ischaemic Maculopathy:** Foveal avascular zone is horizontally oval and measures 300-400. The following changes are seen.
   - Enlargement of foveal avascular zone.
   - Irregularity of foveal avascular zone.
   - Capillary budding into foveal avascular zone.
   - Widening of intercapillary spaces and capillary dropouts in the perilfoveal area.\(^8\)

**Age Incidence**

In our study the predominant age group affected is the 51-60 years range 32% followed by 61-70 years range 26% and 41-50 years range 22%. In our study 54% cases are aged between 41-60. This correlates with the Wisconsin Epidemiologic Study of Diabetic Retinopathy, which revealed diabetic retinopathy more prevalent in the middle aged and elderly population affecting people aged 45 to 64 years.\(^9\)

**Table 1/Sex Incidence**

The ratio of males-to-females in our study is 2.85:1. The predominant age group in which males and females were affected was between 51-60 years. The WISCOSIN epidemiological study of diabetic retinopathy (1984) showed male, female ratio was 1.5:1.\(^10\)

**Table 2/Laterality**

In our study, 92% of the patients had bilateral involvement. This exemplifies the fact that Diabetic Maculopathy affects both eyes, although asymmetrically.\(^11\)

**Systemic Ailments**

UKPDS study established that increased blood pressure increases the risk for the development and progression of diabetic retinopathy. Diabetic nephropathy is a risk factor associated with progression of retinopathy and maculopathy. Cardiovascular disease (IHD) accelerates the progression of maculopathy, which is evident in our study, as there is a strong association (85%) of ischaemic maculopathy.
