ABSTRACT

We present a detailed multi-wavelength study (from rest-frame UV to far-IR) of narrow-band (NB) selected, star-forming (SF) Hα emitters (HAEs) at $z \sim 2.23$ taken from the High Redshift(Z) Emission Line Survey (HiZELS). We find that HAEs have similar SED-derived properties and colors to sBzK galaxies and probe a well-defined portion of the SF population at $z \sim 2$. This is not true for Lyα emitters (LAEs), which are strongly biased towards blue, less massive galaxies (missing a significant percentage of the SF population). Combining our Hα observations with matched, existing Lyα data we determine that the Lyα escape fraction ($f_{\text{esc}}$) is low (only $\sim 4.5\%$ of HAEs show Lyα emission) and decreases with increasing dust attenuation, UV continuum slope, stellar mass, and star formation rate (SFR). This suggests that Lyα preferentially escapes from blue galaxies with low dust attenuation. However, a small population of red and massive LAEs is also present in agreement with previous works. This indicates that dust and Lyα are not mutually exclusive. Using different and completely independent measures of the total SFR we show that the Hα emission is an excellent tracer of star formation at $z \sim 2$ with deviations typically lower than 0.3 dex for individual galaxies. We find that the slope and zero-point of the HAE main-sequence (MS) at $z \sim 2$ strongly depend on the dust correction method used to recover SFR, although they are consistent with previous works when similar assumptions are made.

Key words: galaxies: stellar populations, multi-wavelength; galaxies: high redshift

1 INTRODUCTION

A wide variety of multi-wavelength surveys indicate that the rate at which galaxies form stars has changed with cosmic time, increasing by about one order of magnitude from $z \sim 0$ to $z \sim 1-2$, when the cosmic star formation had a likely maximum (Lilly et al. 1996; Pérez-González et al. 2005; Hopkins & Beacom 2006; Karim et al. 2011; Sobral et al. 2013). A similar behavior is found for the specific star-formation rate (sSFR), the ratio between star-formation rate (SFR) and stellar mass at a given stellar mass (Noeske et al. 2007; Dutton et al. 2010; Magdis et al. 2010; Sobral et al. 2014). However, there is still some debate about the behavior at $z > 2-3$, since there are several uncertain factors involved in the analysis, such as dust correction factors or the contribution of emission lines in the determination of stellar mass (Bouwens et al. 2009, 2012; Stark et al. 2013; González et al. 2014).

In agreement with the evolution of the cosmic SFR, the molecular gas content of star-forming (SF) galaxies is also higher at $z \sim 2$ than at lower redshifts, although the star-formation efficiency is claimed to not strongly depend on cosmic epoch (Tacconi et al. 2010).
2 I. Oteo et al.

The main conclusion of this work is the analysis of the properties of HAEs at \( z \sim 2.23 \) selected from the High Redshift (Z) Emission Line Survey (HiZELS) (Geach et al. 2008; Sobral et al. 2009b,c, 2012, 2013, 2014). HiZELS uses a set of NB filters in NIR bands to look for emission-line galaxies up to \( z \sim 9 \). The study of HAEs will also allow to analyse the accuracy of the H\( \alpha \) emission as a proxy of SFR and the relation between SFR and stellar mass at \( z \sim 2 \). Combining the H\( \alpha \) observations with available, matched Ly\( \alpha \) data we will also study the Ly\( \alpha \) escape fraction and its relation with galaxy properties.

This paper is organized as follows. In §2 we present the data sets used, the selection of our sources, and how we analyse them. In §3 we study the nature of HAEs and compare them with LAEs, LBGs, and \( sBzK \) galaxies to place HAEs into the context of SF galaxies at the peak of cosmic star formation. In §4 we study the population of galaxies with both Ly\( \alpha \) and H\( \alpha \) emission and analyse the Ly\( \alpha \) escape fraction at \( z \sim 2 \). We examine in §5 the accuracy of H\( \alpha \) emission as a tracer of star formation at \( z \sim 2 \) and in §6 we explore the location of our galaxies in an SFR-mass plane and discuss in detail the uncertainties in the determination of the slope of the main-sequence (MS) of star formation at \( z \sim 2 \). Finally, the main conclusions of the work are summarized in §7.

Throughout this paper all stellar masses and SFRs reported are derived by assuming a Salpeter IMF. We assume a flat universe with \( \Omega_m, \Omega_\Lambda, h_0 = (0.3, 0.7, 0.7) \), and all magnitudes are listed in the AB system (Oke & Gunn 1983).

2 METHODOLOGY

2.1 Data sets

Due to the availability of multi-wavelength data and NB Ly\( \alpha \) and H\( \alpha \) observations over an overlapping redshift range, we focus in this work on the COSMOS field (Scoville et al. 2007). In order to sample the SEDs and study the stellar populations of the galaxies analysed in this paper (see §2.2), we take optical to NIR photometry from Ilbert et al. (2013), mid-IR IRAC and MIPS data from the S-COSMOS survey (Sanders et al. 2007), and Herschel PACS and SPIRE data from Pep and HerMES projects, respectively (Lutz et al. 2011; Oliver et al. 2012). High-quality photometric redshifts for the studied galaxies are taken from Ilbert et al. (2013), GALEX (Zamojski et al. 2007) and CHANDRA (Elvis et al. 2009) data will be also used.

2.2 Source selection

The main objective of this paper is the analysis of the properties of NB-selected HAEs at \( z \sim 2.23 \). In some Sections of this paper we will use a sample of LAEs, LBGs, and \( sBzK \) galaxies at \( z \sim 2 \) to help understand the properties of HAEs place them into the context of the SF population at \( z \sim 2 \). In this Section we explain how all these galaxies were selected.

The samples of HAEs and LAEs are taken from Sobral et al. (2013) and Nilsson et al. (2009), respectively. LAEs and HAEs were selected via the NB technique, with an NB filter centered at
3963 Å (129 Å width) for LAEs and at 2.121 μm (210 Å width) for HAEs. In addition to the NB criterion, HAE selection requires identification of the detected emission-line as Hα at z ∼ 2.23 rather than other line emitters at different redshifts. This selection includes a BzK cut to remove low-redshift interlopers, a Lyman-break like cut to remove z ∼ 3.3 [OIII] emitters, and inclusion of double and triple line emitters from the combination of all HiZELS NB filters. It should be pointed out that the sBzK criterion applied to HAEs does not produce the loss of galaxies with unusual colors, but it is used to increase the completeness of the sample. Also, it might be possible that a small number of HAEs has been missed because of their extremely blue SEDs (similar to those for LBGs, see [3]). However, this percentage is estimated to be very low due to the use of double and triple line detections, since blue HAEs would have very strong emission lines and low reddening, and thus be detectable in [OII] or [OIII] as well as Hα (see Sobral et al. 2013, for more details).

Completeness analysis indicates that LAEs are 90% complete down to a Lyα flux of f_{\text{Lyα}} \sim 6 \times 10^{-17} \text{erg cm}^{-2} \text{s}^{-1} (Nilsson et al. 2009) and HAEs are 90% complete down to an Hα flux of f_{\text{Hα}} \sim 5.6 \times 10^{-17} \text{erg cm}^{-2} \text{s}^{-1} (Sobral et al. 2013). We recall at this point that the Lyα and Hα NB filters used in Nilsson et al. (2009) and Sobral et al. (2013), respectively, select galaxies over an overlapping redshift range. The Lyα filter is broader than the Hα filter in the redshift space and, therefore, selects galaxies over a wider redshift range, with the redshift range of HAEs being fully included within the redshift range of LAEs. The great advantage is that it will be possible to study galaxies with both Lyα and Hα emission even if Lyα has a velocity offset with respect to Hα (see [3]).

It is important to point out that among the whole sample of 187 LAEs of Nilsson et al. (2009), only 118 have a counterpart in the Ilbert et al. (2013) catalog, the data set that we use for optical-to-NIR SED fits. This represents 63% of the sample. The non-detections are mainly a consequence of the blue nature of these LAEs, that are clearly detected in U, B, r, or i bands, but are very faint in z and redder bands. The non detection in the NIR is an indicator of their low stellar mass, being less massive than HAEs and other SF galaxies detected in the NIR. The significant number of LAEs without NIR counterpart indicates that the Lyα technique tends to select low-mass, blue galaxies. Accurate SED fits cannot be carried out for those faint LAEs due to the lack of near-IR information that is essential for age, stellar mass, and redshift estimations. Stacking might be an alternative, but it has been reported that stacking in LAEs does not provide reliable estimations of the median properties of the population (Vargas et al. 2014). Therefore, we have decided not to include these LAEs in the analysis. This might bias our results since we only include in the final sample the most massive LAEs selected through the NB technique in Nilsson et al. (2009). We will indicate the implications of this in the relevant sections of the paper.

Regarding HAEs, most of them have a counterpart in the Ilbert et al. (2013) catalog, with only 8% being undetected. The non-detections are mainly due to the faintness of that small population of HAEs in optical bands. At the same time this is an indication that the HAE selection is also able to identify very dusty sources that might be missed in optical-based studies. We do not include the previous 8% of faint HAEs in our analysis since their UV continuum cannot be well constrained. They represent a very low percentage of the total sample and, therefore, their exclusion is not expected to affect significantly the conclusions presented in this work. However, it should be noted that due to their red colors (e.g. high dust extinction) they might be a significant proportion of dust-extinguished HAEs.

The nature of Hα emitters at z ∼ 2.23

LBGs and BzK galaxies are taken from Oteo et al. (2014). LBGs were selected with the classical dropout technique, where the NUV and U bands were used to sample the Lyman break at z ∼ 2 and a U-V color was used to avoid contamination from low-redshift interlopers. Furthermore, non detection in the GALEX UV band was imposed. The BzK galaxies were selected using the criterion of Daddi et al. (2004), that picks up both SF galaxies (sBzK galaxies) and quiescent galaxies (pBzK galaxies). Since we are interested in galaxies dominated by star formation, we only consider sBzK galaxies for most of the analysis presented in this work, although pBzK galaxies will be used for a comparison in some discussions. While LAEs and HAEs have a narrow redshift distribution due to their selection with NB filters, LBGs and sBzK have redshifts spanning typically 1.5 < z < 2.5 (Daddi et al. 2004; Oteo et al. 2014). Therefore, in order to carry out a fairer comparison with LAEs and HAEs at z ∼ 2.23, we additionally limit the photometric redshift of LBGs and sBzK galaxies to 2.0 < z_{\text{phot}} < 2.5. This redshift range has been selected to account for the uncertainties of photometric redshift determinations at z ∼ 2.25 (Ilbert et al. 2013). To avoid a possible presence of any low-redshift interlopers in the HAE and LAE samples, we also limit their photometric redshifts to the same range: 2.0 < z_{\text{phot}} < 2.5. Again, this range is chosen to account for the z_{\text{phot}} uncertainties.

We clean all samples from AGN contamination by removing all sources with X-ray CHANDRA detections (Elvis et al. 2009). It should be pointed out that the percentage of X-ray detections in our galaxies is low, less than 5% in all the four samples studied. Additionally, we use GALEX photometry (Zamojski et al. 2007) to clean our samples from low-redshift interlopers. At z ∼ 2 the Lyman break is redshifted out of the UV regime and, therefore, our galaxies cannot be detected in GALEX bands.

After all these considerations, we end up with a sample of 373 HAEs, 69 LAEs, 3751 LBGs, and 13194 sBzK galaxies. We note that out of all the samples, HAEs are the ones drawn from the smallest volume, followed by LAEs, LBGs, and sBzK galaxies. Thus, the number of galaxies in each sample is largely driven by the different volumes. The number density of HAEs is 4.8 \times 10^{−3} Mpc$^{-3}$ down to log (L_{\text{Hα}}) > 42.0 and the number density of LBGs is 1.6 \times 10^{−4} Mpc$^{-3}$ down to log (L_{\text{Hα}}) > 42.3. The number density of LAEs obtained here is smaller than the value reported in Nilsson et al. (2009), mostly due to our inclusion of the criterion to clean the sample from lower-redshift interlopers and because we only include in the sample galaxies detected in the NIR. Furthermore, the value reported in Nilsson et al. (2009) was calculated over 28% of the area covered by their observations, which in turn represents 2% of the entire area of the COSMOS field. This makes their calculation very uncertain due to the influence of cosmic variance. The number density of LBGs is 3.1 \times 10^{−4} Mpc$^{-3}$, and the number density of sBzK galaxies is the highest in our samples, 1.1 \times 10^{−3} Mpc$^{-3}$, due to the high number of sources selected. Also note that LBGs and sBzK have different, more uncertain SFR limits.

2.3 Analysis

In the rest-frame UV to NIR regime we analysed the nature of our selected galaxies via the traditional SED-fitting technique with Bruzual & Charlot (2003) (hereafter BC03) templates. To this end we used LePhare (Arnouts et al. 1999; Ilbert et al. 2006). We included the emission lines in the stellar population templates (Schaerer & de Barros 2009; de Barros et al. 2014) since we are working with SF galaxies and, in fact, LAEs and HAEs are selected
through their emission lines. The strength of the Lyα emission is more uncertain than other emission lines due to its resonant nature. Therefore, we do not include U-band information in the fits. This does not significantly change the values of the SED-derived properties, since the UV continuum is well sampled with the other filters. In this way, the filters used in the fits are: Subaru B, V, r, i′, z′, and VISTA Y, J, H, and Ks (Ilbert et al. 2009, McCracken et al. 2012). IRAC data for the IRAC-detected galaxies are also included (Sanders et al. 2007).

The BC03 templates used in this work were built by assuming an exponentially declining SFH and a fixed metallicity $Z = 0.2Z_\odot$. We considered time scale $\tau_{\text{SF}}$ values of 0.1, 0.2, 1.0, 2.0, 3.0, and 5.0 Gyr. We chose a fixed value for metallicity because this parameter tends to suffer from large uncertainties (see for example de Barros et al. 2014). For age we considered values ranging from 10 Myr to 3.4 Gyr, the age of the Universe at the median redshift of our galaxies. Ages were taken in steps of 10 Myr from 10 to 100 Myr, in steps of 20 Myr from 100 to 200 Myr, in steps of 50 Myr from 200 to 500 Myr, in steps of 100 Myr from 500 Myr to 1 Gyr, and in steps of 0.2 Gyr from 1.0 to 3.4 Gyr. Dust attenuation was included in the templates via the Calzetti et al. (2000) law and parameterized through the color excess in the stellar continuum, $E_b(B-V)$, for which values ranging from 0.0 to 0.7 in steps of 0.05 were considered.

Once the templates are fitted, the rest-frame UV luminosity for each galaxy was obtained from its normalized best-fitted template and converted to $SFR_{\text{UV}}$ via the Kennicutt (1998) calibration. Note that $SFR_{\text{UV}}$ is not corrected for dust attenuation. The UV continuum slope was obtained by fitting a power-law function to the UV continuum of each best-fitted template. Figure 1 shows the SED fit results for six HAEs randomly selected from our sample. For a reference, the best-fitted templates with no inclusion of emission lines (fitted with LePhare as well) are also included. It can be seen that emission lines have a clear effect on the observed fluxes and the best-fitted rest-frame optical continuum emission. This is because the strongest rest-frame optical emission lines are sampled with some broad-band filters used in the fits: Hα is within the $K_s$ band, [OIII]5007 within the $H$ band, and [OIII]727 within the $J$ band. While the rest-frame UV SEDs are similar in all the cases, fainter rest-frame optical continua are obtained when including the effect of emission lines. This translates into lower stellar masses and younger ages.

Among the whole sample of SF HAEs, only nine are individually detected in any of the Herschel bands. This represents a detection rate of 3%. Interestingly, despite being very low, the percentage of Herschel detections is higher for HAEs than for LBGs ($\sim 0.7\%$) or sBzK galaxies ($\sim 0.5\%$). This indicates that the Hα selection can recover not only relatively dust-free, but also highly dust-obscured sources. However, the comparison between the number of Herschel detections and physical properties is challenging since at $z \sim 2$ Herschel only selects the most extreme galaxies rather than normal SF galaxies. Source confusion is also a major problem when analysing the FIR emission of UV, optical, or NIR-selected galaxies. We have attempted to identify source confusion by analysing the optical ACS images of the galaxies along with the MIPS-24 $\mu$m and VLA contours. As an example, see results in Figure 2 for the three SPIRE-500 $\mu$m-detected HAEs. The size of the images are 40″ on each side, slightly larger than the SPIRE-500 $\mu$m beam, the Herschel band with the largest PSF. In the three cases, the location of the MIPS detection is coincident with a radio emission, indicating that there is no significant contribution of nearby FIR-bright sources that might contaminate the fluxes in SPIRE bands.

The contamination is even more unlikely in PACS bands, since their PSF is 2–4 times smaller than SPIRE beams. As a sanity check for SPIRE-detected sources, we have re-done the FIR SED fits including only their less-likely contaminated PACS photometry. The values obtained for the total IR luminosity, and hence for $SFR_{\text{IR}}$, are in agreement with those including SPIRE data within the uncertainties ($\sim 0.1$–0.2 dex). It should be pointed out that there are two LAEs individually detected in Herschel but they are also detected in X-ray and, consequently, have a likely AGN nature and are not considered in this work (see §3 and Bongiovanni et al. 2010).

The IR SEDs of the FIR-detected galaxies are fitted with Chary & Elbaz (2001) (CE01), Dale & Helou (2002), Polletta et al. (2007), and Berta et al. (2013) templates. As an example, we show in Figure 3 the IR SEDs of the three HAEs detected in SPIRE-500 $\mu$m. The presence of the rest-frame 1.6 $\mu$m stellar bump (sampled with the IRAC bands at the redshift of our galaxies) is clear in the three galaxies, indicating that their SEDs are dominated by star formation. All the different templates fit well the IR SEDs of the galaxies, with similar values of $\chi^2$. We choose to report the results obtained with CE01 templates, as in many previous works in the literature. The best-fitted CE01 templates are integrated between rest-frame 8 and 1000 $\mu$m to derive total IR luminosities, $L_{\text{IR}}$. These are then converted into SFR by using the Kennicutt (1998) calibration. The total SFR is then obtained by assuming that all the light absorbed by dust in the UV is reemitted in the FIR: $SFR_{\text{total}} = SFR_{\text{UV}} + SFR_{\text{IR}}$.

Since most galaxies are not individually detected in the FIR, we also performed stacking analysis in Herschel bands to study the FIR emission of Herschel-undetected galaxies (see for example Ibar et al. 2013, for stacking analysis in HAEs at $z \sim 1.47$). One single band near the peak of the dust SED is enough to estimate the total IR luminosity. We focused on the PACS-160 $\mu$m band for stacking due to its relatively small beam and employ the residual maps, as in many previous works. We stacked by using the publicly available IAS Stacking Library (Béthermin et al. 2010) and uncertainties in the stacked fluxes were derived by using bootstraps. For HAEs, we stacked in different bins of stellar mass (from log ($M_*/M_\odot$) = 9.5 to 11 in bins of 0.5 dex) and dust-corrected Hα-derived SFR ($SFR_{\text{H\alpha}}$) from log ($SFR_{\text{H\alpha}}$[$M_\odot$ yr$^{-1}$]) = 1.0 to 2.0 in bins of 0.5). Those bins cover the whole range of values for those parameters. For $sBzK$s, where the number of sources is high and allows stacking over more stellar mass bins, we stacked from log ($M_*/M_\odot$) = 9.8 to 11.6 in bins of 0.2 dex.

We only detected stacked fluxes for HAEs in the bin corresponding to the highest stellar mass (10.5 $\leq$ log ($M_*/M_\odot$) $<$ 11), where 66 galaxies are included and the stacked flux is $f_{160\mu m} = 1.4 \pm 0.3$ mJy, corresponding to log ($L_{\text{IR}}$/L$_\odot$) = 11.8 $\pm$ 0.1) and highest SFR$_{\text{H\alpha}}$ (1.5 $\leq$ log ($SFR_{\text{H\alpha}}$) $<$ 2.0, where 166 sources are included and the stacked flux is $f_{160\mu m} = 1.0 \pm 0.2$ mJy, corresponding to log ($L_{\text{IR}}$/L$_\odot$) = 11.3 $\pm$ 0.1). This is consistent with more massive SF galaxies being more affected by dust, in agreement with Garn & Best (2010), Sobral et al. (2012) or Ibar et al. (2013), although it could be also due to a pure scaling of the SED. We also stacked LAEs as a function of stellar mass (with the same bins as for HAEs), but no stacked detections are recovered probably due to the low number of sources producing poor statistic and also to the less dusty nature of LAEs (see also §3). In sBzK galaxies we recover detections for $9.8 < $ log ($M_*/M_\odot$) $<$ 11.0 with more than 1000 galaxies in each bin. The recovered stacked fluxes are summarized in Table 2.3. The stacked PACS-160 $\mu$m fluxes were converted into $L_{\text{IR}}$ by using single band extrapolations with CE01 templates.
The nature of Hα emitters at \( z \sim 2.23 \)

Figure 1. Examples of SED fit results for 6 randomly-selected HAEs from our sample. These fits are representative of the whole sample of HAEs studied in this work. The best-fitted BC03 templates including emission lines are shown in orange, and best-fitted templates with no emission lines are in green. Red open squares are the observed photometric data. Due to the uncertain contribution of the Ly\( \alpha \) emission, the \( U \) band information has not been included in the fits. Our HAEs (and also LAEs) are selected for having strong H\( \alpha \) (and Ly\( \alpha \)) emission. Therefore, it is expected that emission lines affect their observed fluxes. It can be seen in this figure that the best-fitted templates including emission lines have fainter rest-frame optical continua and, therefore, represent less massive galaxies. If templates with no emission lines had been used, the stellar masses would have been overestimated. The UV continuum (and hence SFR\(_{\text{IR}}\)) of the best-fitted templates does not change significantly when emission lines are included.

Figure 2. Analysis of source confusion and contamination at FIR wavelengths from nearby sources in the three SPIRE-500 \( \mu \)m-detected HAEs. The MIPS-24 \( \mu \)m (green), and VLA (yellow) contours are over-plotted in the ACS I-band images of the galaxies. HAEs are located in the center of each image. Images are 40″ on each side, slightly larger than the SPIRE-500 \( \mu \)m beam, the Herschel band with the largest PSF. The VLA and MIPS detections, that have better spatial resolution than PACS and SPIRE, indicate that there is no significant contribution of possible nearby FIR-bright sources that might contaminate the HAE Herschel fluxes. The PSF of PACS bands is much smaller than the SPIRE PSFs, so contamination is even more unlikely.

Table 1. Stacked PACS-160 \( \mu \)m fluxes and their associated total IR luminosities for our sample of sBzK galaxies at \( 2.0 < z_{\text{phot}} < 2.5 \).

| Stellar mass range | Stacked \( f_{160\mu m} \) | \( \log (L_{\text{IR}}/L_\odot) \) |
|--------------------|--------------------------|-------------------------|
| \( 9.8 \leq \log (M_\star/M_\odot) < 10.0 \) | 0.53 ± 0.05 mJy | 11.4 ± 0.1 |
| \( 10.0 \leq \log (M_\star/M_\odot) < 10.2 \) | 0.80 ± 0.06 mJy | 11.5 ± 0.1 |
| \( 10.2 \leq \log (M_\star/M_\odot) < 10.4 \) | 1.00 ± 0.09 mJy | 11.6 ± 0.1 |
| \( 10.4 \leq \log (M_\star/M_\odot) < 10.6 \) | 1.20 ± 0.12 mJy | 11.7 ± 0.1 |
| \( 10.6 \leq \log (M_\star/M_\odot) < 10.8 \) | 1.23 ± 0.12 mJy | 11.7 ± 0.1 |
| \( 10.8 \leq \log (M_\star/M_\odot) < 11.0 \) | 1.40 ± 0.17 mJy | 11.8 ± 0.1 |

and errors were obtained from the flux uncertainties. SFR\(_{\text{IR}}\) were obtained with the [Kennicutt (1998)](kennicutt1998) calibration.

3 THE NATURE OF H\( \alpha \) EMITTERS AT \( z \sim 2 \)

Figure 4 shows the SED-derived dust attenuation, stellar mass, UV continuum slope, and dust-corrected SFR of our HAEs at \( z \sim 2.23 \). It can be seen that HAEs can be either dust-poor (and have blue UV slopes) or dusty (and have red UV slopes) and have a wide range of stellar masses and dust-corrected SFR. This already indicates that our sample of SF HAEs, selected down to a fixed dust-uncorrected SFR, is not significantly biased towards any SED-derived property. The distributions of SED-derived properties of HAEs resemble those for sBzK galaxies, one of the classical populations traditionally used to study galaxy properties at \( z \sim 2 \). However, HAEs seem to have slightly higher stellar masses and SFR on average, probably due to their selection based on SFR. The distributions for HAEs contrast to those found for LAEs, which have much lower dust attenuation and stellar mass and much bluer UV continuum.

Figure 3. IR SEDs of the three SPIRE-500 µm-detected HAEs as an illustration of the SED-fitting results for the Herschel-selected galaxies studied in this work. We plot the observed photometry in $K_s$, the four IRAC bands, MIPS-24 µm, PACS, and SPIRE. The best fitted Chary & Elbaz (2001), Polletta et al. (2007), Dale & Helou (2002), and Berta et al. (2013) templates are also shown, with the color code indicated in the bottom-right legend. In the SED fits, a redshift of $z = 2.23$ has been assumed. The data provide a good sampling of the dust emission peak in HAEs at $z \sim 2.23$. Therefore, the integration of the best-fitted templates between 8 and 1000 µm provides an accurate determination of their total IR luminosities and, consequently, dust-corrected SFR. No significant difference is found for $L_{IR}$ when using different templates. We choose to report results obtained with Chary & Elbaz (2001) templates, as in many previous works.

Figure 4. From left to right: Dust attenuation, stellar mass, UV continuum slope, and dust-corrected total SFR of our selected HAEs (orange filled histograms). We include the distributions obtained for LAEs, LBGs, and SBzK galaxies. These properties were obtained by fitting BC03 templates to the observed multi-wavelength photometry (from $B$ to IRAC bands, when available) of each galaxy. The BC03 templates were built by assuming an exponentially declining SFH and a fixed metallicity of $Z = 0.2 Z_\odot$. Emission lines were also included in the templates. Histograms have been normalized to their maxima in order to clarify the representations. The distributions indicate that HAEs and SBzK galaxies have similar stellar populations, both in the median values and in the range covered. HAEs have a very-well defined selection criterion and, therefore, represent an excellent sample for studies of star formation at $z \sim 2$. LAEs are significantly biased towards blue, less massive, and dust-poor galaxies. slopes on average. This indicates that Ly$\alpha$ and H$\alpha$ samples are formed, on average, by galaxies with different stellar populations (although the values obtained for LAEs are within the distributions found for HAEs). This suggests that the selection based on Ly$\alpha$ is much more biased than the selection in H$\alpha$ and that using Ly$\alpha$ to select high-redshift galaxies might lead to the loss of a significant population at a given redshift (mostly the reddest and most massive galaxies). Figure 4 shows that the sample of LBGs is also slightly biased towards galaxies with lower dust attenuation and bluer UV continuum slope, although the effect is not as strong as it is for LAEs.

Figure 5 shows the relation between color and stellar mass for our HAEs. We choose the $Y - K_s$ color because it matches at $z \sim 2$ with the rest-frame $u - r$ color traditionally used to define the blue cloud and the red sequence in the local Universe (see for example Strateva et al. 2001). Defining a clear difference between the blue cloud and red sequence at $z \sim 2$ is challenging due to the low number of passive galaxies populating the red sequence. However, we consider here that $p$BzK galaxies represent the prototype of passive galaxies populating the red sequence at $z \sim 2$. These galaxies are also represented in Figure 5. HAEs cover a wide range of colors and stellar masses and, thus, they represent a diverse population with a range of properties. H$\alpha$ selection only misses a small population of the bluest and least massive galaxies at $z \sim 2$.25. Some SF HAEs have colors even similar to $p$BzK galaxies, as happens for obscured galaxies with intense, obscured star formation (Oteo et al. 2013b, 2014).

Interestingly, although most galaxies with Ly$\alpha$ emission have
low dust attenuation and blue colors, there is a population of 12 red LAEs with \( \log \left( M_*/M_\odot \right) > 10.25 \). Their stellar masses are as high as the most massive HAES. All 12 red LAEs are detected in IRAC and there is no indication of power-law like MIR SEDs, so these red LAEs are SF galaxies rather than AGNs (note that AGN contamination in all our samples was avoided by discarding galaxies with X-ray detection). This population represents a low fraction of the whole LAE sample, but it indicates that Ly\( \alpha \) emission can also escape from dusty, red systems, as previously reported from individual detections in FIR wavelengths.

It is also important to examine the overlap between HAES and other populations of SF galaxies at \( z \sim 2.25 \). In other words: what is the fraction of galaxies of a given type which could have been selected/missed through any of the other criteria? This study has been already done for LBGs, UV-selected, and sBzK galaxies in Oteo et al. (2014). In that work, it was concluded that most LBGs can be also selected through the sBzK criterion and only 25% of sBzK galaxies would have been selected as LBGs (mainly due to the bias of the Lyman-break selection towards UV-bright galaxies). Consequently, sBzK galaxies are a better representation of the bulk of SF galaxies over \( 1.5 < z < 2.5 \) than LBGs.

Figure 5 represents the classical color-color diagram employed to select high-redshift BzK galaxies, both SF and passively evolving (Daddi et al. 2004). Studying the location of our selected HAES in such a diagram gives information about the overlap between those populations. Most HAES can be also selected as sBzK galaxies. As commented in §2.2, this was expected for HAES since a BzK selection was applied in Sobral et al. (2013) to the NB-selected HAES to avoid contamination from low-redshift interlopers. HAES cover the same range of colors than sBzK galaxies confirming that they are not strongly biased either towards dust obscured or dust-free objects. However, as suggested by Figure 5 the H\( \alpha \) selection might miss the bluest galaxies (now in terms of their \( z-K \) color) at \( z \sim 2.25 \), as it happens to sBzK galaxies. Actually, there is a sub-population of "blue" LBGs with \( \text{BzK} = (z-K)_\text{AB} - (B-z)_\text{AB} \leq -0.2 \) and \( (B-z)_\text{AB} < 1 \) that cannot be selected as sBzK galaxies. This is mainly due to their blue \( z-K \) color for their \( B-z \) color. At \( 2 < z < 2.5 \), the \( z-K \) color samples the Balmer and 4000 \( \AA \) breaks and, therefore, is a proxy of the age of the galaxies: younger galaxies should have bluer \( z-K \) colors. This is further confirmed by the shape of their optical SEDs and ages, since 80% of the blue LBGs are younger than 100 Myr (always under the assumption of exponentially declining SFH and 0.22\( Z_\odot \) metallicity and with the caution of the degeneracies between age, SFH, dust attenuation, and metallicity) with nearly flat photometric redshift distributions. Most LAEs are blue and less massive, but there is a small population of LAEs with red colors. Although the number of such red LAEs is not high, it indicates that Ly\( \alpha \) emission can also escape from dusty, red systems, as previously reported from individual detections in FIR wavelengths.
Figure 7. Median SEDs of the HAEs, LAEs, LBGs and sBzK galaxies studied in this work. Bottom-right panel shows the median SEDs renormalized to unity at 2.5 μm. In order to explore the EW of the Lyα emission in each sample we show the region around Lyα in the upper-left panel. In this panel, the location of Lyα emission is indicated with a vertical dashed line. This Figure shows that LBGs have a bright rest-frame UV continuum, whereas sBzK galaxies are the most attenuated on average. Except for the difference in the normalization factors, the median SED of HAEs and sBzK galaxies are similar, in agreement with the similarity in their stellar populations. The upper-left panel indicates that the Lyα emission boosts the U-flux only in LAEs, indicating that LBGs, HAEs, and sBzK galaxies do not have strong Lyα with high equivalent width, on average.

A significant percentage of HAEs cannot be selected as LBGs due to their faint rest-frame UV continuum. This indicates that a significant population of galaxies with intense Hα emission, and thus actively forming stars, would be missed if only the drop-out criterion had been applied. This, along with the relatively high percentage of sBzK galaxies that could be missed in the drop-out criterion used in this work, suggests that the Lyman-break technique employed in this work is biased towards UV-bright galaxies and, consequently, would not be adequate for studying the properties of a complete census of galaxies at the peak of star formation. This result is important for evolutionary studies (Stott et al. 2013, Sobral et al. 2014).

To further analyse the properties of our HAEs we study now their median rest-frame UV-to-optical SED and compare it to the median SED of LAEs, LBGs, and sBzK galaxies. The median SEDs were built from the median fluxes in each photometric band. Then, following the same procedure presented in §2.3 we fitted their observed fluxes with BCO3 templates including emission lines. In these fits we did not include the U band photometry because it might be potentially contaminated by the uncertain strength of the Lyα emission, not included in the templates. The results are shown in Figure 7. Apart from the normalization factor, the shape of the median SED of HAEs and sBzK galaxies is similar, supporting previous results derived with SED-derived properties and observe colors. The SED of HAEs constrain with the median SED of LAEs, which is much bluer, similar to what it happens to LBGs. This reinforced previous claims that Lyα selection is strongly biased and might miss a significant percentage of the SF population at the peak of cosmic star formation.

As commented above, the U band might be affected by the uncertain strength of the Lyα emission. The top-left inset plot in Figure 7 shows the region of the SED around the Lyα emission. It can be seen that the U-band magnitudes of HAEs, LBGs, and sBzK galaxies agree well with the best-fitted templates. Therefore, in these galaxies the equivalent width of the Lyα emission is not high enough to alter significantly the U-band fluxes. This indicates that HAEs, LBGs, and sBzK galaxies do not have Lyα emission with high equivalent width on average. This is not the case for LAEs. The median U-band flux of LAEs is brighter than the predicted by the templates, suggesting intense Lyα emission with high equivalent widths as expected by their selection. These results indicate that the Lyα emission has high equivalent width only in a small sample of galaxies, reducing the chances of finding strong Lyα emission in a general population of SF galaxies at z ∼ 2. Our selected LBGs have higher rest-frame UV luminosities than the other galaxies analysed in this work. Their lack of strong Lyα emission, on average, is thus in agreement with the results reported in Schaerer et al. (2011), who found that, at a given redshift, the Lyα emission is more common in galaxies with fainter UV magnitudes (see also Stark et al. 2010).

It should be pointed out that the comparison between the different samples presented in this work is very dependent on the depth of the surveys used to select them. However, COSMOS is one of the deepest sets of multi-wavelength data available. Therefore, it makes a good judgement of the biases that affect samples selected at z ∼ 2 through the studied selection criteria for most deep extragalactic surveys. One alternative to overcome this limitation would be using the lensing power of massive clusters of galaxies, as was done in Alavi et al. (2014), allowing to detect galaxies much fainter than previous surveys at z ∼ 2. However, the latter is not the traditional way of selecting LAEs, sBzK, or HAEs as normally they are searched and analysed in well-known cosmological fields where a wealth of deep multi-wavelength observations are available for their analysis.

4 MATCHED Lyα AND Hα EMITTERS: THE Lyα ESCAPE FRACTION AT z ∼ 2.23

Of special interest is the analysis of the galaxies which exhibit both Lyα and Hα emission (Lyα-Hα emitters, LAHAEs), not only due to the low number of such sources reported so far at z ∼ 2, but also because they allow to constrain the escape fraction of Lyα photons (Hayes et al. 2010a, Song et al. 2014). As indicated in §2.3 we can study LAHAEs because the Lyα and Hα NB filters used in Nilsson et al. (2009) and Sobral et al. (2013) select galaxies within an overlapping redshift slice over the same region of the sky. The Lyα observations select galaxies over the redshift range 2.206 ≤ z_{Lyα} ≤ 2.312. The Hα observations cover 2.216 ≤ z_{Hα} ≤ 2.248. The Lyα observations cover a wider redshift range than the Hα observations. Therefore, if HAEs had strong Lyα emission, they should have been detected in the Lyα filter.

In the overlapping region of the COSMOS field observed by the Lyα and Hα NB filters there are 158 HAEs and 146 LAEs. We should point out that we include here the whole sample of LAEs, both detected and undetected in near-IR wavelengths. The reason is that we are interested here in the fraction of HAEs with Lyα emission, not in the SED-derived properties of galaxies with Lyα emission (for which only...
The nature of Hα emitters at $z \sim 2.23$

However, there are only 7 galaxies in common between the two samples. Therefore, only 4.5% of HAEs have strong enough Lyα emission to be selected as LAEs. This implies very low Lyα escape fraction at $z \sim 2$ and agrees with Hayes et al. (2010a), who found six LAHAEs in their sample, implying an average Lyα escape fraction of $\sim 5\%$. These results reinforce the different nature of the galaxies selected through the Hα and Lyα NB techniques and highlight the low chance of finding galaxies with Lyα emission, at least at $z \sim 2.23$. It should be remarked that the Hayes et al. results are based on Lyα observations about 10 times deeper than those used in this work. Similarly, the Hα survey in Hayes et al. (2010a) is about 2 times deeper than HiZELS. However, we cover in this work an area of the sky that is about 20 times higher than in Hayes et al. (2010a). Therefore, the results complement each other in different regimes of Lyα and Hα brightness and area surveyed. We have explicitly indicated in Figure 6 the location of LAHAEs. Among the seven joint detections, six have blue $B - z$ colors compatible with almost flat UV continuum, whereas one of them has a red SED. Apart from the red LAHAE with SED-derived $E_\alpha(B-V) \sim 0.5$, the remaining LAHAEs have a median dust attenuation of $E_\alpha(B-V) \sim 0.15$. Their ages range within $1 - 900$ Myr.

We derive the Lyα escape fraction in our LAHAEs from the ratio between the intrinsic and observed Lyα luminosities and assuming case B recombination, so the intrinsic Lyα emission can be obtained from the intrinsic (dust-corrected) Hα luminosity. In order to make a fair comparison with previous works, the Hα luminosity is corrected for dust attenuation by using the SED-derived $E_\alpha(B-V)$:

$$f_{\text{esc}} = \frac{L_{\text{obs}}(\text{Ly}\alpha)}{8.7 \times L_{\text{obs}}(\text{H}\alpha) \times 10^{0.4 \times E_\alpha(B-V) \times k(\lambda_{\text{H}\alpha})}} \times 10^{0.4 \times E_\alpha(B-V) \times k(\lambda_{\text{H}\alpha})}$$

In the previous equation we have assumed that $E_\alpha(B-V) = E_\alpha(B-V)$, as it has been reported in several previous works to happen at high redshift (see for example Reddy & Steidel 2004; Erb et al. 2006; Reddy et al. 2010). However, it should be remarked that this has not been proven accurately, and will represent one of the major sources of uncertainties in our derived Lyα escape fraction. This uncertainty affects not only our results but also the results reported in most previous works at similar redshifts, since a relation between $E_\alpha(B-V)$ and $E_\alpha(B-V)$ must be assumed.

In Figure 8 we represent the Lyα escape fraction as a function of the SED-derived dust attenuation, UV continuum slope, stellar mass, and dust-corrected SFR for our LAHAEs at $z \sim 2.23$. For a comparison we also represent the nine LAHAEs reported in Song et al. (2014) with both Lyα and Hα emission (UV continuum slopes are not provided for individual galaxies in Song et al. 2014). To be consistent, we take the observed Lyα and Hα fluxes and the SED-derived properties from Song et al. (2014) and then the Lyα escape fraction is calculated with the previous equation. However, we note that the selection criteria are not the same in both samples. Here we use the classical NB technique to look for LAEs and HAEs, whereas the LAEs in Song et al. (2014) were found through blind spectroscopy and then followed-up with near-IR spectroscopic observations. Actually, the Lyα luminosities of the LAHAEs in Song et al. (2014) are higher than for the LAHAEs presented in this work. Despite these differences, the Lyα escape fractions derived in both works agree well.

It can be seen from Figure 8 that the Lyα escape fraction decreases with increasing dust attenuation, as previously reported at similar and lower redshifts (Hayes et al. 2014; Atek et al. 2014; Song et al. 2014), and also with increasing (redder) UV continuum slope (a proxy for dust attenuation) and higher stellar mass and SFR. We also include in Figure 8 the upper limits on the Lyα escape fraction in those HAEs whose Lyβ is not detected. These upper limits have been calculated assuming a limiting Lyα EW of 80 Å (Nilsson et al. 2009). The upper limits indicate that the relations found for LAHAEs corresponds to the upper envelope of the actual correlations. However, upper limits also indicate that the highest Lyα escape fraction seen at low dust attenuation and/or UV continuum slopes are not seen at higher dust attenuation and/or UV continuum slopes. These results indicate that Lyβ emission preferentially escapes from blue, low-mass galaxies with low dust attenuation (with the exception of a low percentage of massive, red and dusty LAEs as obtained in §3). This is in agreement with the SED-derived properties and colors found for LAEs in previous sections. It should be noted that the number of LAHAEs at $z \sim 2$ reported so far is low and, consequently, matched Lyα-Hα surveys over larger areas of the sky are needed to increase the number of LAHAEs and have more robust results with higher statistical significance.

5 Hα SFR VS UV AND UV+IR: A CONSISTENT VIEW

The Hα emission is an excellent tracer of instantaneous star formation and calibrations between the SFR and the Hα luminosity have been proposed in the literature (see for example Kennicutt 1998). The Hα emission is affected by dust attenuation (although to a much lesser extent than, for example, the UV). Therefore, in order to derive the total SFR from Hα, accurate dust correction factors are needed. In the local universe, where a significant percentage of galaxies can be detected in the FIR or their Hα and Hβ emissions can be measured, the dust correction factors can be determined with acceptable accuracy. However, this is much more challenging for galaxies in the high-redshift Universe, complicating the determination of the total SFR.

We examine in this section the robustness of the Hα emission as a tracer of SFR at $z \sim 2.23$ for our HAEs. We first compare the results obtained from Hα and UV estimates of the SFR when dust correction is not taken into consideration. This is shown on the left panel of Figure 9. As it can be seen, the two tracers of star formation give significantly different results, with the Hα-derived SFR being higher than the obtained from the rest-frame UV luminosity. The median values found are SFR$_{\text{H}α} = 13.7 \pm 9.0 M_\odot$ yr$^{-1}$ and SFR$_{\text{UV}} = 7.4 \pm 6.6 M_\odot$ yr$^{-1}$, where the uncertainties represent the interquartile ranges.

In the right panel of Figure 9 we show the comparison between Hα-derived and UV-derived SFR when dust correction is included. We correct the rest-frame UV luminosities by using the relation between the dust attenuation and UV continuum slope derived in Heinis et al. (2013), as in §3. The dust correction of the Hα luminosity has been derived by using the relation between stellar mass and dust attenuation of Garn & Best (2010), that has been suggested to be valid for HAEs at least up to $z \sim 1.5$ (Sobral et al. 2012; Ibar et al. 2013; Domínguez et al. 2013; Price et al. 2014).

In the right panel of Figure 9 it can be seen that there is a very good agreement between the UV-derived and the Hα derived SFRs, despite these being calculated with completely different and independent estimators at different wavelengths. The difference between the two estimators is typically lower than 0.3 dex for individual galaxies. Furthermore, both estimations agree quite well.
when galaxies are averaged over different bins of Hα-derived SFR or stellar mass. This result shows the robustness of the Hα emission as tracer of SFR at $z \sim 2$, which adds to the unbiased and well-understood selection function of the Hα NB method to find SF galaxies at different redshifts (Sobral et al. 2012).

Previous works have also analysed the accuracy of Hα emission to recover SFR at high redshift, for example (Erb et al. 2006) and Reddy et al. (2010). They correct from dust attenuation derived from SED fitting, $E_{\alpha}(B-V)$, and assuming $E_{\alpha}(B-V) = E_W(B-V)$, where $E_W(B-V)$ is the reddening for nebular emission. They actually obtained that the traditionally employed relation $E_{\alpha}(B-V) = 0.4 \times E_W(B-V)$ (Calzetti et al. 2000) produces Hα-SFR that over-predict those derived from the X-ray and dust-corrected UV emissions. Recently, Steidel et al. (2014) apply a relation between $A_{H\alpha}$ and $E_{\alpha}(B-V)$ that depends on the value of $E_W(B-V)$. The main advantage of our dust correction method for Hα emission is that we do not require any assumptions about the relationship between $E_{\alpha}(B-V)$ and $E_W(B-V)$, which is still until debate and have been suggested to be redshift-dependent (Kashino et al. 2013). Instead, we use a relation between dust attenuation and stellar mass that has been reported to be valid at least up to $z \sim 1.5$ for HAEs (Sobral et al. 2012).

We also compare in the right panel of Figure 9 the Hα-derived total SFR with the total SFR obtained with direct Herschel detections for the 9 PACS/SPIRE-detected HAEs. As it can be seen, the Hα emission, after the dust correction has been included, is not able to recover the more accurate SFR derived with PACS detections. This is because, at $z \sim 2$, Herschel only detects the most extreme sources for which our average dust correction factor applied to the Hα luminosity are not high enough (due to very high internal obscuration) to reproduce the more accurate Herschel-derived SFR. This also happens to the dust correction factors derived from the UV continuum slopes in high-redshift Herschel-selected galaxies (see for example Oteo et al. 2013; Rodrigiro et al. 2014). Stacking as a function of the Hα-derived total SFR we only recover one $>3\sigma$ stacked detection, also represented in the right panel of Figure 9. The total SFR derived from the PACS stacked flux is higher (in about $\sim 0.3$ dex) with respect to the Hα-determination. This might indicate that the dust-correction factor used to correct the Hα emission is more uncertain for the most massive HAEs with the highest SFRs, although deeper FIR data would be needed to confirm this trend to more normal SF galaxies with lower SFR.

6 SFR VERSUS STELLAR MASS RELATION AND ITS UNCERTAINTIES AT $Z \sim 2$

6.1 The main sequence for HAEs at $z \sim 2$

Most previous works agree that there is a relation between SFR and stellar mass, commonly referred to as the main sequence (MS), where normal SF galaxies are located (see Speagle et al. 2014 for a recent compilation). The MS has been reported to exist from the local universe up to high-redshift and to be relatively independent of environment (Koyama et al. 2013). However, less is known about...
the values of its zero point and slope at a given redshift. One of the main reasons is the lack of FIR detections for a representative population of SF galaxies at each redshift, that prevents accurate determinations of the total SFR. Even with the deepest FIR surveys carried out so far (see for example Elbaz et al. 2011), only a very small fraction of the galaxies are detected in the FIR, mostly at the highest redshifts (Oteo et al. 2013a, 2014). Furthermore, it is claimed that most high-redshift FIR-detected galaxies are not normal SF galaxies, but likely have a starburst nature and are preferentially located above the MS (Rodighiero et al. 2013a; Lee et al. 2013; Oteo et al. 2013a, 2014). Therefore, even with *Herschel*-selected galaxies it is not possible to determine the slope and zero point of the MS at high redshift.

Now that we have evidence from §5 that the Hα emission is a good tracer of star formation at $z \sim 2.23$, that Hα provides a clean, well-understood, SFR-selected sample (not biased to either just blue or just red galaxies), that HAEs are an excellent representation of the whole population of SF galaxies at $z \sim 2$ (§3), and that their stellar masses cover a wider range than many previous studies at $z \sim 2$, we can attempt to study the relation between SFR and stellar mass and its uncertainties by using our sample of HAEs. This is shown as the orange points in Figure 10 with the best-fit MS indicated by the red line.

The main caveat of the analysis of the MS with our sample of HAEs is that they are selected down to a fixed SFR$_{\text{Hα-uncorr}}$ ($\sim 3M_\odot\,\text{yr}^{-1}$) and EW cut, Sobral et al. 2013a. Furthermore, the SFR$_{\text{Hα-corr}}$ of HAEs is obtained by using a dust correction factor which depends on the relation between dust attenuation and stellar mass. All of this means that, for a given stellar mass, only HAEs with SFR$_{\text{Hα-corr}}$ above a certain limit (that is dependent on stellar mass) are included in the sample. This might produce a flattening of the MS with respect to previous works based on other selection functions. In order to explore this in more detail, we have obtained the limiting SFR$_{\text{Hα-corr}}$ in different bins of stellar mass. This is represented in Figure 10 with the open black squares and the dashed curve. As expected, the limiting curve tracks along the locus of the bottom of the points corresponding to HAEs. As an example, our Hα selection would not be able to detect galaxies on the MS relation of Daddi et al. 2007 (solid black line on Figure 10) that have stellar masses log $(M_*/M_\odot) > 9.5$ (but note that dust correction factors used to recover total SFR are different in Daddi et al. 2007 and this work). If our Hα observations would have selected galaxies down to a lower SFR$_{\text{Hα-uncorr}}$, we could have been able to select galaxies with lower SFR$_{\text{Hα-corr}}$ at that stellar mass and, consequently, we might have obtained a steeper MS. This reflects the effect of our Hα selection on the slope of the MS at $z \sim 2$ and should be taken into account in any comparison with the results presented in the literature for galaxies selected in a different way. However, as it will be shown in the next Section, when we use the same methods that in other works to determine the SFR$_{\text{Hα-corr}}$ and stellar mass, the MSs are in very good agreement.

It is clear from Figure 10 that an MS for HAEs exists at log $(M_*/M_\odot) > 9.25$: more massive HAEs have higher SFRs on average. However, the scatter is significant and it increases with stellar mass. It can be also seen that the MS is flatter for more massive galaxies. Actually the relation becomes almost flat at
log$(M_*/M_\odot)$ $\geq 10.2$, where the width of the MS is also higher. Since HAEs are selected by star formation, they are truly SF galaxies: all HAEs with log$(M_*/M_\odot)$ $\geq 10.0$ would also have been selected as SF galaxies according to the sBzK criterion. Therefore, the flattening is not caused by the presence of massive quiescent galaxies without star formation. This flattening of the MS towards massive galaxies can be also seen in Oteo et al. (2014) at $z \sim 1.5$ in their work about stacking analysis in Herschel bands, although the flattening found in this work is much more significant (see also Oteo 2014, Whitaker et al. 2014, or Schreiber et al. 2014). By fitting a linear relation for galaxies with log$(M_*/M_\odot)$ $\leq 10.25$ in the form log$(SFR_{H\alpha - corr}) = a + b \times \log (M_*/M_\odot)$ we find $a = -3.65 \pm 0.15$ and $b = 0.52 \pm 0.02$. This MS is in very good agreement with the results shown in Zahid et al. (2012) in a sample of spectroscopically confirmed H\alpha emitters over a similar stellar mass range than our sample. This is the most comparable sample to ours that can be found in the literature in terms of both H\alpha emission and stellar mass range. Kashino et al. (2013) obtained a higher MS slope with a spectroscopically confirmed sample of galaxies with H\alpha emission, but their galaxies are at a slightly lower median redshift than HAEs in this work and their sample is restricted to more massive galaxies, mainly with log$(M_*/M_\odot)$ $> 10$. Our MS has a lower slope than the classical MS found in Daddi et al. (2007) (D07), probably produced by our selection effect, although different dust-correction factors and recipes for stellar mass determination might play a significant role. This will be discussed in more detail in §6.2.

PACS-detected HAEs are all well above the HAE MS, as happens for PACS-detected LBGs and sBzK galaxies (Oteo et al. 2014; Rodighiero et al. 2014). This indicates that they have an SB nature and do not belong to the population of normal SF galaxies at $z \sim 2$. Actually, our PACS-detected sBzK galaxies have even higher SFRs than those in Oteo et al. (2014) due to the shallower PACS data in COSMOS (Lutz et al. 2011). When stacking as a function of stellar mass, we only recover one detection for HAEs, also represented in Figure 10. The stacked point is in agreement with the D07 MS and it is located slightly above the MS for HAEs found in this work. This is compatible with the previous result that the SFR derived from stacking is slightly higher than the derived from H\alpha in the most massive HAEs. For comparison, we also show the stacked points corresponding to the sample of sBzK galaxies. Only the most massive sBzK galaxies are detected through stacking. The stacked points for sBzK galaxies agree very well with the extrapolation of the MS for log$(M_*/M_\odot)$ $\leq 10.25$ HAEs towards higher stellar masses. However, the most massive stacked sBzK galaxies have higher SFR than the most massive HAEs. This difference might be due to the fact that the dust correction factor employed to recover the total SFR might not be accurate for the most massive galaxies. However, it could also be as a consequence of a different nature between HAEs and sBzK galaxies for the most massive objects. The latter would be supported by the shape of their UV-to-NIR SEDs (see Figure 7), since massive HAEs are bluer than massive sBzK galaxies.

As already obtained in galaxies selected through the Ly\alpha technique tend to be less massive than HAEs. Furthermore, the Ly\alpha selection allows to probe down to lower dust-corrected SFRs. This can be used to extend the MS obtained for HAEs down to log$(M_*/M_\odot)$ $\sim 9$. This is represented by the blue filled squares in Figure 11. As in [3] the dust-corrected SFR for LAEs has been obtained by assuming the IRX-\beta relation of Heinis et al. (2013). Interestingly, and despite the effect of our Hz selection on the MS slope, the point for LAEs agrees very well with the extrapolation of the HAE-MS to lower stellar masses.

### 6.2 Uncertainties in the SFR-mass relation

In order to study the uncertainties involving the determination of the slope and zero-point of the HAE MS at $z \sim 2$ and try to explain in more detail the differences found with previous works, we compare now the SFR-mass relation when considering different recipes used in the literature to obtain stellar mass and total SFR. We focus first on the dependance of the HAE MS upon the recipe used for determining stellar mass. This is shown in Figure 11 where all the SFRs have been derived by correcting the rest-frame UV luminosity with the IRX-\beta relation of Meurer et al. (1999) for the sake of homogenity with previous works that will be referred to in this Section. Therefore, the main difference would be only the determination of stellar mass. We include in Figure 11 the MS when the stellar mass of HAEs is obtained through our method of SED fits with BC03 templates associated to exponentially declining SFHs and the inclusion of emission lines (blue open squares, see [23]).
and also (orange dots) that obtained using the calibration between \( BzK \) photometry and stellar mass reported in Daddi et al. (2004) (see also Rodighiero et al. 2014). It can be clearly seen that the slope of the HAE MS depends upon the method used for deriving stellar mass, with the slope being lower when stellar masses are derived with SED fits with inclusion of emission lines. The top-left inset plot of Figure 11 compares the stellar masses derived with BC03 templates including the effect of emission lines with the derived with the Daddi et al. (2004) calibration. It can be seen that they are correlated but do not follow the one-to-one relation, and the red line is the linear fit to the points. This figure indicates that the definition of the MS (slope and normalization) depends on the way stellar mass is calculated.

When using the same dust correction factors and recipe for stellar mass determination than in DO7, we find a MS slope closer to their result (cf. orange and black lines in Figure 11). The still slightly lower MS slope might be explained by the \( \mathrm{H}\alpha \) selection effect (see §6.1). We also plot in Figure 11 the stacked points for HAEs and \( sBzK \) galaxies at their same redshift: NB-selected HAEs or \( sBzK \) galaxies are used for their characterization.

Figure 12 shows the impact of different dust correction factors in the definition of the HAE MS at \( z \sim 2 \). With the aim of avoiding any uncertainty coming from the determination of stellar mass we represent the SFR-mass relation by using the rest-frame \( K \) band luminosity. This luminosity is a proxy of stellar mass (Drory et al. 2004) and is a direct observable quantity that does not need any assumption or calibration in its determination. Three different methods for deriving the total SFR have been employed: 1) dust-corrected \( \mathrm{H}\alpha \) luminosity with the local dust-mass relation (red points); 2) dust corrected rest-frame UV luminosity with the IRX-\( \beta \) relation of Heinis et al. (2013) (orange filled dots); 3) dust corrected rest-frame UV luminosity with the IRX-\( \beta \) relation of Meurer et al. (1999) (blue filled dots). Note that the only difference in Figure 12 is the methods adopted for deriving the total SFR. It can be seen that the MS is strongly affected by the different dust corrections, with the slope being steeper with the dust correction based on the Meurer et al. (1999) relation. The MS derived from the \( \mathrm{H}\alpha \) emission assuming the local dust-mass relation and from the rest-frame UV with the dust correction based on the relation of Heinis et al. (2013) are similar due to the agreement between both SFR indicators (see Figure 9). For a reference, we show in the inset panel of Figure 12 the relation between stellar mass and rest-frame \( K \) band luminosity for the two different assumptions for stellar mass determination used in the discussion above.

Summarizing, our results show that, despite there is evidence that the MS exists, its slope and zero points at each redshift are challenging to determine. Their values depend on the recipes employed to obtain stellar mass and total SFR. For given assumptions of these, consistent values can be determined provided that representative samples of sources such as NB-selected HAEs or \( sBzK \) galaxies are used for their characterization.

7 CONCLUSIONS

In this work, we have carried out a multi-wavelength analysis (from the rest-frame UV to the FIR) of the spectral energy distribution (SED) of narrow-band (NB) selected, star-forming (SF) \( \mathrm{H}\alpha \) emitters (HAEs) with the aim of analysing their physical properties and their importance for galaxy formation and evolution. We have also compared their physical properties with those derived for other classical populations of SF galaxies at their same redshift: NB-selected Ly\( \alpha \) emitters (LAEs), Lyman-break galaxies (LBGs), and \( sBzK \) galaxies. The main conclusions of our work are the following:

(i) The HAE selection recovers the full diversity of SF galaxies at \( z \sim 2 \). Coupled with the simple and well-understood HAE selection (selecting SF galaxies down to a given dust-uncorrected SFR) which can be self-consistently applied at multiple redshift slices from the local Universe up to \( z \sim 2.5 \), HAEs represent an excellent sample to study galaxy evolution.

(ii) At the depth of the COSMOS data, only about 30% of \( sBzK \) galaxies can be selected with the drop-out technique, whereas 95% of LBGs can be selected with the \( sBzK \) criterion. Only 4.5% of HAEs can be selected as LAEs. These results indicate that the Lyman-break and Ly\( \alpha \) selections miss a relevant percentage of the SF population at the peak of cosmic star formation. LBGs and LAEs are biased towards blue, less massive galaxies. Although the
fits with BC03 templates (green) and calibration with low percentage of the SF population at interpret results at higher redshifts where only Ly \( \alpha \) emissions considered in the analysis, these results are important to in-slope and zero point. These deviations are close to zero when averaging the sample in stellar mass or SFR bins.

(vii) By using the \( \text{H}\alpha \)-derived SFR we study the relation between SFR and stellar mass for our HAEs. We find a main-sequence (MS) of star formation, but with a slope lower than the classical Daddi et al. (2007) relation. By fitting a linear function in the form: log SFR = \( a + b \times \log (M/M_\odot) \), we obtain: \( a = -3.65 \pm 0.15 \) and \( b = 0.52 \pm 0.02 \). We show that, in part, the lower slope with respect to previous works might be due to the different selection criteria. However, exploring the uncertainties in the slope and zero point of the HAE MS, we find that they are very sensitive to both the dust correction factors adopted to recover the total SFR and the way the stellar masses are determined. This largely explains the difference with previous works and represent the main uncertainty in the definition of MS at high redshift. This might apply to any sample of SF galaxies. Using the same recipes for stellar mass calculation and dust correction as Daddi et al. (2007) we find consistent results for the MS at \( z \sim 2 \) for our HAEs and also for sBzK galaxies whose total SFR are obtained with a stacking analysis in Herschel bands.

ACKNOWLEDGMENTS

The authors acknowledge the anonymous referee for their detailed and constructive report which has improved the presentation of the results. IO and RJI acknowledge support from the European Research Council (ERC) in the form of Advanced Grant, COSMICISM. DS acknowledges financial support from the Netherlands Organisation for Scientific research (NWO) through a Veni fellowship, from FCT through a FCT Investigator Starting Grant and Start-up Grant (IF/01154/2012/CP0189/CT0010) and from FCT grant PEst-OE/FIS/UI2751/2014. IRS acknowledges support from STFC (ST/I00075X/1), the ERC Advanced Investigator programme DUSTYGAL 321334 and a Royal Society/Wolfson Merit Award. PNB acknowledges support from STFC. Herschel is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA. The Herschel spacecraft was designed, built, tested, and launched under a contract to ESA managed by the Herschel/Planck Project team by an industrial consortium under the overall responsibility of the prime contractor Thales Alenia Space (Cannes), and including Astrium (Friedrichshafen) responsible for the payload properties of these galaxies and shed light on how Ly \( \alpha \) can escape from these systems.

(v) The median SEDs of the galaxies studied in this work reveal that the Ly \( \alpha \) emission is strong enough to affect the broad-band \( U \) photometry only in LAEs. This result indicates that Ly \( \alpha \) emission is not strong in LBGs, HAEs, or sBzK galaxies on average, highlighting the low probability of finding Ly \( \alpha \) emission in a general sample of selected SF galaxies.

(vi) Only 4.5% of HAEs show detectable Ly \( \alpha \) emission implying low Ly \( \alpha \) escape fraction at \( z \sim 2 \) in agreement with previous results. Additionally, we find that the Ly \( \alpha \) escape fraction (fe) decreases with increasing SED-derived dust attenuation, the UV continuum slope, stellar mass and SFR. This suggests that Ly \( \alpha \) preferentially escapes from blue galaxies with low dust attenuation, although a population of red LAEs is also present indicating that dust and Ly \( \alpha \) are not mutually exclusive.

This figure indicates that dust-correction factors (Daddi et al. 2004) (blue). The black line would correspond to mass-to-light ratio equal to unity. Green and blue straight lines are fitted to the green and blue points, respectively. This figure indicates that dust-correction factors have a strong influence on the definition of the MS at \( z \sim 2 \), both in the slope and zero point.

(iii) There is a significant percentage of LAEs that are not detected in optical and near-IR broad band filters even with the deep photometry used in this work. The non detection indicates that these galaxies have a faint continuum but strong emission lines. Due to their non detection, SED fits cannot be carried out for these galaxies and, consequently, their properties and, most importantly, their contribution to galaxy evolution studies, are unknown.

Figure 12. Relation between total SFR and the rest-frame \( K \) band luminosity for our sample of HAEs at \( z \sim 2.23 \). Different estimators of the total SFR have been used: dust-corrected H\( \alpha \) luminosity with the local dust-mass relation (red dots) and dust-corrected UV rest-frame luminosity with the Heinis et al. 2013 (blue) and Meurer et al. 1999 IRX-\( \beta \) (orange) relations. The inset panel shows the relation between the stellar mass and the rest-frame \( K \) band luminosity for two different recipes for stellar mass: SED fits with BC03 templates (green) and calibration with \( z \) and \( K \) magnitudes (Daddi et al. 2004) (blue). The black line would correspond to mass-to-light ratio for our sample of HAEs at \( z \sim 2 \).
