ABSTRACT

Composite materials of polyethylene terephthalate with silanized halloysite nanoclay were prepared and characterized. Halloysite was first functionalized with benzoyloxypropyltrimethoxysilane and then incorporated it into the polymer matrix via melt extrusion at 0.5, 1, and 2 wt% clay load ratios. The modified clay was characterized by means of elemental carbon quantification, thermogravimetric analysis, X-ray diffraction, and nitrogen adsorption–desorption. The silanization was confirmed to have taken place with an approximate reaction yield of 5%. While the silanization did not significantly affect the crystal structure or the morphological properties of the clay, a mass loss starting from 190 °C attributed to the organosilane compound used to modify the clay was observed in the reacted samples, along with increased thermal stability. The composite materials exhibited an increase in Young’s modulus and a decrease in the ultimate strain, but not a significant change in the oxygen permeability of the composites with respect to the neat PET.
Introduction

The development of polymeric composite materials with lower gas permeability than the matrix has garnered attention in recent years, as a lower gas permeability can increase the shelf life of food products by delaying the inward diffusion of oxygen that can spoil the freshness of the contained product or the outward diffusion of CO₂ in carbonated beverages. Polyethylene terephthalate (PET), a polyester resin possessing good tensile strength, impact strength, optical clarity, and thermal stability, is the most widely used material in bottling liquid products for human consumption. In particular, clay minerals have been studied as filler candidates in polymer composites to reinforce the mechanical properties of the material and reduce permeability for packaging applications [1–3].

The use of clay minerals as fillers, such as halloysite (HNT) and montmorillonite (MMT), has attracted interest due to their natural origin and low cost [4, 5]. Halloysite is an aluminosilicate clay mineral with the formula Al₂Si₂O₅(OH)₄·nH₂O consisting of a double layer of tetrahedral silicon oxide on the outside and octahedral aluminum oxide on the inside, rolled up into a hollow tubular shape. The chemical modification of halloysite with an organosilane coupling agent with specific functional groups can lead to better dispersion of the clay in the polymer matrix [6, 7]. Variables such as the chemical structure of the organosilane, or the reaction conditions of the functionalization reaction, can affect the way the organosilane attaches to the nanotubes, and consequently, the way the modified clay interacts with the matrix [8, 9].

These interactions are especially important since an improved dispersion of the filler in the polymer might lead to a reduced gas permeability of the material by increasing the tortuous path, the gas molecules of the diffusing substances must overcome to pass through the matrix [10–14]. However, low matrix–filler compatibility and the sensitivity of PET to degradation due to humidity, high temperature, and shear stresses during melt processing are aspects that must be considered to create a viable PET composite material [15, 16].

Studies on improving the barrier properties of PET have been conducted employing composites containing neat and chemically modified montmorillonite clays [17]. The results share a trend where composites containing MMT clay modified with organic salts are better than neat MMT due to a better dispersion of the clay layers throughout the material [18, 19]. An additional modification of the clay material with oleic acid further enhanced the gas barrier properties of the final composite due to an even better dispersion of the clay in the matrix and to the carboxylic acid serving as a scavenger for oxygen molecules diffusing through the material [20].

Halloysite clay can serve as a cheaper alternative to montmorillonite in polymer/clay composites [5]. To the best of our knowledge, the only work on PET/HNT composites was reported by Gorrasi et al. [21].
who studied these materials intended for bottling applications and concluded that although the incorporation of the clay in the PET matrix reinforces the mechanical properties of the material, the agglomerated clay particles act as nucleation centers when the material is cooled after melt compounding, making the material overall prone to crystallization and to be brittle and opaque: properties not desirable in bottles.

To address this area of opportunity, we studied the silanization of halloysite nanoclay with benzoyloxypropyltrimethoxysilane (BOPTMS) to improve the clay’s compatibility with the polymer matrix and its dispersion in the material. The enhanced dispersion will, in turn, enhance the gas barrier properties of the composite without compromising the material’s mechanical properties and optical clarity. The decrease in the barrier properties could be attributed to an increase in the tortuosity of the gas going through the matrix as well as through the nanoparticle that could be interpreted as the nanotube capacity to absorb gas [22].

Methodology

Materials

Halloysite nanoclay with a surface area of approximately 50 m²/g and ethanol (99.97%) were purchased from Sigma-Aldrich (México). Benzoyloxypropyltrimethoxysilane (BOPTMS, 99%) was purchased from Gelest, Inc. (North Carolina, United States). Toluene (99.94%) was purchased from CTR Scientific (Monterrey, México). Bottle-grade polyethylene terephthalate resin (PET, Cleartuf 8006) with an intrinsic viscosity of 0.8 dL/g was supplied by Continentes IEM, S.A. de C.V. (Monterrey, México). All materials were used without further purification.

Halloysite functionalization

In a typical halloysite functionalization procedure, 2 g of clay was dried at 200 °C for 12 h before the reaction. Once dry, the clay was suspended in 15 mL of dry solvent (toluene or acetone) and ultrasonically dispersed for 30 min under a dry atmosphere to reduce particle size. The system was then heated at half of the solvent’s boiling temperature, and 2.1 mL of BOPTMS was dissolved in 10 mL of solvent and added into the reaction system dropwise under constant stirring. The mixture was then refluxed for 12 h with continuous stirring under a dry atmosphere at 119 °C for toluene and 56 °C for acetone. The modified clay was then thoroughly washed with dried toluene and ethanol to remove any present unreacted organosilane. Finally, the product was cured at 120 °C for 12 h, collected and preserved in a dry atmosphere. A schematic representation of the reaction can be found in Fig. 1. The nomenclature used for the studied functionalized halloysite samples was established as HNT_200_X, where X stands for the reaction solvent (A for acetone and T for toluene). HNT stands for a blank halloysite sample that was not dried or reacted, and HNT_200 represents a clay sample that was dried, but not reacted with the organosilane.

PET/HNT composite preparation

Previous to processing, the materials were dried at 70 °C under vacuum for 24 h to remove water that may promote polymer degradation during processing. The composites were prepared by loading the polymer at 0.5, 1, and 2 wt% with halloysite clay and extruding the materials with an Intelli Plasti-Corder Brabender Torque Rheometer coupled to a three-zone twin-screw extruder at temperatures of 270 °C for zones I and II and 265 °C for zone III and a screw speed of 50 rpm with an average residence time of 70 s.

The 1-mm-thick samples used for the oxygen permeation and mechanical characterization were injected after the extrusion with a Nissei FNX80 machine at an injection speed of 55 mm×s⁻¹, an injection time of 9 s, a holding pressure of 58.8 MPa, screw speed of 80 rpm, mold pressure of 0.8 MPa, and a cooling time of 20 s. Heating was divided into four zones kept at temperatures of 260, 270, 280, and 290 °C, the nozzle at 290 °C, and the mold at 10 °C.

Elemental carbon analysis

The quantification of elemental carbon on functionalized samples was carried out on a Thermo Scientific Flash2000 Organic Elemental Analyzer. The amount of elemental carbon was used to determine the grafted BOPTMS, and this, in turn, was used to estimate the reaction yield. Therefore, for each BOPTMS molecule (284.38 g × mol⁻¹), the number of carbon atoms (12.01 g × mol⁻¹) is 10. The reaction yield was
calculated using the grafted BOPTMS on the samples and compared to the BOPTMS (1.104 g cm\(^{-3}\)) initially added.

**X-ray diffraction (XRD)**

X-ray diffraction was carried out on a Rigaku Mini-flex 600 Powder X-ray diffractometer. The measurements were carried out with a source voltage of 30 kV and 15 mA using a Cu cathode (K\(\alpha\)) as the source at a wavelength of 1.54 Å. The diffraction patterns were measured from 3 to 60\(^\circ\) with a step of 0.05 and a scanning rate of 2 \(^\circ\) min\(^{-1}\). No specific sample preparation was required.

**Thermogravimetric analyses (TGA)**

Thermogravimetric analyses were carried out on a TA Instruments Thermal Analysis Q500 instrument. The samples were heated from 30 to 800 °C at a heating rate of 10 °C min\(^{-1}\). A nitrogen atmosphere was used when heating the samples from 30 to 600 °C, and an oxygen atmosphere was used from 600 °C onwards.

**Nitrogen adsorption–desorption**

Nitrogen adsorption–desorption was carried out on a Quantachrome Novatouch NT1LX–1 instrument. Specific surface areas were calculated with the Brunauer–Emmett–Teller (BET) method, and total pore volume and pore size distributions were calculated with the Barrett–Joyner–Halenda (BJH) method. The samples were degassed under 25 mTorr with heating at 10 °C min\(^{-1}\) from room temperature to 60 °C, held at this temperature for 1 h, then heated at 5 °C min\(^{-1}\) to 110 °C, and held at this temperature for 4 h.

**Composite mechanical properties**

The mechanical behavior of the composites was studied with an Instron 3365 uniaxial testing machine on type V bone-shaped specimens. The samples were tested at a deformation rate of 10 mm/min at an initial clamp separation of 12.7 mm at 25 °C.

**Oxygen permeability**

Oxygen permeability of the composites was studied with a Mocon Ox-Tran 2/61 tester. The exposed area of the samples was 10 cm\(^2\), and the thickness of the samples ranged from 0.8 to 1 mm. A mixture of 98% N\(_2\) and 2% H\(_2\) was used as a carrier gas. The instrument was calibrated with a standard Mylar polyester film before sample measurements.

**Table 1** Results of elemental carbon analysis data of dried and functionalized halloysite samples

| Sample          | Elemental C (%) | Rxn. yield (%) |
|-----------------|-----------------|----------------|
| Neat            | Treated         |                |
| HNT_200 (Blank) | Not detected    |                |
| HNT_200_T       | 1.99 ± 0.12     | 2.50 ± 0.75    | 4.07 ± 0.26 |
| HNT_200_A       | 2.72 ± 0.42     | 2.61 ± 0.34    | 5.56 ± 0.86 |
Results

Elemental carbon analysis

The results on elemental carbon quantification, as well as the calculated BOPTMS functionalization reaction efficiency data, are reported in Table 1. Two types of functionalized samples were studied: the samples straight from the functionalization reactions (neat) and samples treated afterward at 280 °C for 5 min to simulate the processing conditions of PET.

Thermogravimetric analysis

The results are shown in Fig. 2. In neat halloysite, a small mass loss was observed at around 130 °C, likely pertaining to weakly bound water on the surface, along with a considerable weight loss (ΔM_D) starting at around 330 °C corresponding to the dihydroxylation of the nanotubes [21]. Two mass losses are observed in dried halloysite: the first starting at 210 °C, likely corresponding to crystallization water present in the sample, and the second one (ΔM_D) corresponding to dehydroxylation starting around 330 °C. In functionalized samples, a mass loss (ΔM_O) starting at (T_1) and continuing until sample dihydroxylation (T_2, ΔM_D) was observed, which presumably corresponds to the decomposition of the organic material [23, 24].

The quantitative TGA results are reported in Table 2, where it can be observed that the organic component of the functionalized clays began to decompose at roughly the same temperature for both samples.

X-ray diffraction

The diffraction patterns of the studied samples are reported in Fig. 3. The diffraction pattern of the neat clay reveals the presence of quartz impurities in the sample, as reported similarly by Yuan et al. [23] and Joussein et al. [25].

The comparison for the spacings in the clay is presented in Table 3. The space between the (0 0 1) planes is reduced by 0.02 nm after drying the samples, and returns to 0.72 nm after the silanization.

Nitrogen adsorption–desorption

The nitrogen adsorption–desorption isotherms of neat halloysite and silanized samples are depicted in Fig. 4. The isotherms were of type IV with H3 hysteresis loops, corresponding to mesoporous materials [26–28]. The calculated values for surface area and pore volume and pore size are reported in Table 4.

Mechanical properties

The results of the mechanical tests of the composites are depicted in Fig. 5.

Oxygen permeability

The oxygen transmission rate (OTR) at 150 h is reported in Table 5. The average permeability of the composite containing functionalized halloysite is almost the same than that of neat PET, meaning that the presence of the functionalized filler has a minimal effect on this property at 0.5% load.

The barrier effect behavior of the materials is depicted on Fig. 6, where no significant difference was observed between the different types of samples. The composite containing non-functionalized halloysite, however, displayed a lower oxygen permeability than the functionalized one.
The carbon elemental analysis results indicate that heating the sample at 280°C for 5 min does not appear to reduce the carbon content significantly, meaning the organic components of the functionalizing agents do not decompose rapidly enough if processed under a similar residence time. It is also apparent that silanizing the clay in acetone yields a higher amount of organic material in the clay. This can be explained through the mechanism in which the organosilane reacts with the different species in the medium. Yuan et al. [23] explained that there are two competing processes: grafting and oligomerization of BOPTMS. Carli et al. [9] also reported that when HNT modification with organosilanes occurred in ethanol, this led to the formation of an oligomerized structure being favored. The polar nature of acetone and the presence of trace amounts of water in

| Sample    | \(d_{001}\) (nm) |
|-----------|------------------|
| HNT       | 0.72             |
| HNT_200   | 0.70             |
| HNT_200_T | 0.72             |
| HNT_200_A | 0.72             |

### Discussion

**Halloysite functionalization**

The carbon elemental analysis results indicate that heating the sample at 280°C for 5 min does not appear to reduce the carbon content significantly,
the solvent can explain the observed results: the organosilane reacted in acetone could have been hydrolyzed readily and then been grafted on the HNTs or oligomerized, with oligomerization being more likely as previous results suggest. Although the difference is less than 2% in reaction yield, this can lead to a cheaper approach to functionalize the clay in terms of the energy required to reflux the mixture, since the boiling point of acetone is approximately half the boiling point of toluene.

Based on the appearance of the mass differential curves, the thermal decomposition of the organic material is a gradual process that does not conclude upon reaching the temperature where

| Sample         | S (m² × g⁻¹) | Pore volume (cm³ × g⁻¹) |
|----------------|--------------|------------------------|
| HNT            | 50.7 ± 0.16  | 0.5 ± 0.01             |
| HNT_200        | 49.2 ± 1.43  | 0.9 ± 0.01             |
| HNT_200_T      | 39.5 ± 0.86  | 0.7 ± 0.11             |
| HNT_200_A      | 33.2 ± 0.89  | 0.5 ± 0.06             |

Table 5 Oxygen transmission results of PET/HNT composites of non-modified and functionalized halloysite samples

Figure 5 Young’s modulus (a), maximum load (b) and strain at maximum load (c) of the PET/HNT composites at different clay loads.
dehydroxylation starts, meaning that both processes overlap for the studied samples. Interestingly, it was observed that the dehydroxylation of the functionalized samples starts at higher temperatures when compared to the clay that was only dried. The greater effect, observed for sample HNT_200_T, has the thermal stability of the clay increased for 80°C. This is surprising, considering that on previously reported results of functionalized halloysite, the functionalized clay starts to dehydroxylate at lower temperatures than neat halloysite [8, 9, 24]. Wang and Huang previously commented on the effect HNTs have on the thermal decomposition of polymer composites, in which the nanotubes help contain and delay the release of volatile species that are generated during thermal degradation, increasing the thermal stability of the composites. The substitution of the clay’s hydroxyl groups through grafting of the organosilane also helps increase the stability of PET composites, since the release of these hydroxyl groups may lead to hydrolytic decomposition of the polymer [21, 29].

The crystal structure of the clay was not significantly affected by the drying nor the silanization reaction. This change in the basal spacing may be attributed to the functionalization reaction [30], but is not significant enough to allow organosilane grafting between the rolled layers of a halloysite nanotube [23]. These results may indicate that the grafting and silane oligomerization takes place on the available silanol groups available on the outer edges of the tube and the available aluminoil groups on the edges and the lumen [8, 9, 23, 24].

The surface area did not change significantly from roughly 50 m² × g⁻¹ after drying the clay before silanizing it. However, it decreased to under 40 m² × g⁻¹ in both reacted samples due to the condensed and deposited silane reducing the surface area. The pore volume grew after drying the clay but was once again reduced after the reaction, perhaps due to the organosilane molecules occupying the space inside the pores and blocking the edges of the nanotubes, as described by Tan et al. [31]. Two main pore size populations were observed: one around 2.6 nm corresponding to slit-shaped mesopores corresponding to the layers of the rolled nanotube that separate and form slit-like pores upon dehydration as reported by Kohyama et al. [32], and a broad distribution centered around 10 nm corresponding to the lumen of the nanotubes. The pore size distribution was not significantly altered after drying the clay at the reported temperatures, which is consistent with the results reported by Yuan et al. [27]. However, the differential pore volume is notably lower in the functionalized samples due to the organosilane molecules reacting with the -OH groups located in the outer edges of the nanotubes and covering them, leaving the lumen as the most abundant pores.

### Halloysite composite mechanical properties

The injected composite samples had a good optical clarity indicative of amorphous samples, as observed on Fig. 7. Although the effect of the clay on Young’s modulus of the composite is not significantly different to that of neat PET, it can be observed that the composite at 2% load has a higher Young’s modulus, a lower ultimate strength (σₘ), and specially a lower ultimate strain (εₘ). Based on these two parameters, it can be said that the composite containing the clay functionalized in toluene has the lowest resilience (σₘ/εₘ) and that a concentration percolation threshold should be between 1 and 2%. Based on this observation, the best silanized sample would be the one functionalized in acetone at a filler load lower than 2% to prevent an alteration of the mechanical properties.

### Halloysite composite gas permeability

The composite samples display the same tendency as neat PET. The observed behavior on Fig. 6 may be indicative that there is a slightly lower permeability.
on non-functionalized composite samples when compared to the functionalized ones. This can be due to the functionalized composites containing halloysite nanotubes with obstructed edges and pores, making gas diffusion inside the tubes difficult and reducing the overall tortuosity of the system. The oligomerization of some organosilane moieties could have also bridged some nanotubes, further blocking gas molecules from diffusing into the tubes. Non-functionalized clay nanotubes, on the other hand, are not chemically bridged and can be separated with the shear work during the composite processing. However, the composite containing functionalized clay has, statistically speaking, the same permeability as if it were no filler was present. This indicates that a deeper study on the dispersion of the functionalized composites is needed.

**Conclusions**

Halloysite clay was functionalized with BOPTMS, and PET composites were prepared at clay loadings of 0.5, 1, and 2% with the objective to improve the gas barrier properties of the material while conserving the same mechanical properties of the neat polymer. The presence of deposited organic material on the clay was assessed by quantifying the organic carbon present in the functionalized samples and TGA. The mass loss at temperatures higher than 190 °C confirmed the presence of organic material within the functionalized samples and an increased thermal stability of the clay material. The drying treatment and silanization reaction did not affect the nanoclay crystal structure significantly. Nitrogen adsorption–desorption shed light on the way the silanizing agent deposited on the nanotubes: the porosity of the sample was reduced after silanization and the abundance of the pores in the sample shifted from the slit-like pores between the nanotubes’ layers to the lumen, indicating the organosilane molecules reacted with the hydroxyl groups located on the edges and inside the lumen of the nanotubes.

The inclusion of the clay in the PET matrix produced a slight change in the mechanical performance of the composite materials in the studied filler concentrations, and a change in the oxygen permeability of the materials was not observed.
