Very recently the atomic masses of neutron-rich Zr isotopes, from $^{96}$Zr to $^{104}$Zr, have been measured with high precision. Using a schematic Interacting Boson Model (IBM) Hamiltonian, the evolution from spherical to deformed shapes along the chain of Zr isotopes, describing at the same time the excitation energies as well as the two-neutron separation energies, can be rather well reproduced. The interplay between phase transitions and configuration mixing of intruder excitations in this mass region is succinctly addressed.

PACS numbers: 21.60.Fw, 27.70.+q

Nuclear masses and binding energies, or more in particular two-neutron separation energies ($S_{2n}$), form a very important observable that characterize a given nucleus and provide information about nuclear correlations providing at the same time a stringent test for nuclear models.

The goal of this paper is to make use of a technique developed in Ref. \cite{1} in order to describe at the same time the energy spectra and $S_{2n}$ values obtained from a very recent experimental study of masses for the neutron-rich Zr isotopes (see refs. Ref. \cite{2, 3}) and nearby Sr and Mo isotopes \cite{4}. This transitional region is of particular interest because a rapid change in the structure of Zr isotopes from mass A=98 and onwards is observed, i.e., a rather sudden change from spherical to well deformed shapes \cite{5, 6, 7}. This region is known for the appearance of deformed intruder states that even become the ground state and initiate the onset of a region of deformed nuclei for the heavier Zr isotopes \cite{8} (beyond N=58). Therefore, a study has been attempted in order to analyze the experimental variation observed in $S_{2n}$ values.

For a theoretical description of the Zr isotopes, encompassing both the low-lying excitations as well as the intruder states, one should be using a very large shell-model configuration space using the corresponding effective nucleon-nucleon interaction \cite{9}. An attempt in that respect has been carried out for $^{92}$Zr \cite{10} using a restricted model space considering both proton and neutron orbitals outside of a $^{88}$Sr core nucleus. In view of the fact that besides neutrons filling the 50-82 shell one would need to consider protons in the 28-40 shell, including proton excitations into the $1g_{9}/2$ configuration, calculations would become unfeasible. Therefore, we start from a strongly truncated model space, however keeping the pairing and quadrupole force components within the Interacting Boson Model (IBM) approximation \cite{11}. This model approximates the interacting many-fermion problem using as the major degrees of freedom, $N$ pairs of valence nucleons that are treated as bosons, carrying angular momentum either 0 (the $s$ bosons) or 2 (the $d$ bosons). This model is very appropriate in order to describe even-even medium-mass and heavy nuclei and transitional nuclei. Even here, treating proton and neutron bosons explicitly, one risks to be involved with too many model parameters. Therefore, in the present description of the Zr isotopes, we make use of an approach in which we restrict to the use of identical bosons. This act of truncation naturally implies that one has to replace the Hamiltonian by an effective IBM Hamiltonian describing the interactions amongst these identical bosons \cite{12}. Our approach here is very similar to a recent study of the Pt nuclei \cite{13}, a region in which there exist clear indications of the presence of intruder excitations.

The IBM Hamiltonian used is composed from a single-boson energy term, a quadrupole and an angular momentum term,

$$\hat{H} = \varepsilon_d \hat{n}_d - \kappa \hat{Q} \cdot \hat{Q} + \kappa' \hat{L} \cdot \hat{L},$$  

(1)

where $\hat{n}_d$ denotes the $d$ boson number operator and

$$\hat{L} = \sqrt{10}(d^\dagger \times \hat{d})^{(1)},$$

(2)

$$\hat{Q} = s^\dagger \hat{d} + d^\dagger \hat{s} + \chi(d^\dagger \times \hat{d})^{(2)}.$$  

(3)

We point out that in more realistic calculations, the values $\varepsilon_d > 0$ and $\kappa > 0$ \cite{14, 15, 16, 17, 18} have been used. Moreover, the $E2$-transition operator is taken to have the same structure of the quadrupole operator $\hat{Q}$ appearing in
the Hamiltonian,

\[ \hat{Q}(E2) = c_{\text{eff}} \hat{Q} \]  

(4)

This approach is known as the Consistent-Q Formalism (CQF) \[13\].

The definition of the two-neutron separation energies is the following (starting from the binding energies):

\[ S_{2n} = BE(N) - BE(N - 1), \]  

(5)

where \( N \) denotes the number of valence nucleon pairs and it is assumed that we are treating nuclei belonging to the first half of the neutron shell (50 – 82) filling up with increasing mass number.

The Hamiltonian \( \hat{H}_\text{eff} \) generates the energy spectrum of each individual Zr nucleus and will be called “local Hamiltonian”. For the correct description of binding energies, one needs to add that part of the Hamiltonian that does not affect the spectrum and that will be called “global Hamiltonian” (and so depends on the total number of bosons only \( \hat{H}_\text{glob} \)). The simplest interpretation of the IBM global part comes from the fact that this part describes the overall smooth varying energy term and can be associated with the structure of the Liquid Drop Model. Therefore, the description we use, within the context of the IBM, is somehow similar to the Strutinsky method \[20, 21\] in the sense that the global part takes care of the major contribution to the nuclear binding energy \( BE \), while the local part, that is, that the global part takes care of the major contribution to the nuclear binding energy \( BE \), while the local part, that is, notably smaller, modulates this global behavior and describes the local correlations. An alternative way to incorporate binding energy effects in the IBM results from explicitly taking into account the \( s \)-boson one-body contribution \( \varepsilon_s \hat{n}_s \) and the \( s \)-boson two-body interaction energy \( u_{0s1/2s1/2} \). One can, however, eliminate these \( s \)-boson terms taking into account the conservation of the number of bosons, giving rise to terms proportional to \( N \) and \( N(N - 1) \) in the binding energies while proportionals to \( N \) in the two neutron separation energies (see Ref. \[22\]). Thus this procedure is equivalent to the method used here and in Ref. \[1\].

The contribution of the global part of the Hamiltonian to the \( S_{2n} \) is expressed as

\[ S_{2n}^\text{gl} = \mathcal{A} + \mathcal{B}N, \]  

(6)

where \( \mathcal{A} \) and \( \mathcal{B} \) are assumed to be constant along a chain of isotopes (see \[1\]). Therefore,

\[ S_{2n}(N) = \mathcal{A} + \mathcal{B}N + BE^{lo}(N) - BE^{lo}(N - 1), \]  

(7)

where \( BE^{lo} \) is the local binding energy derived from the Hamiltonian \( \hat{H}_\text{eff} \).

In order to obtain a global description of the Zr isotopes, we prefer to consider a reduced number of parameters, keeping the Hamiltonian \( \hat{H}_\text{eff} \) as constant as possible when passing from isotope to isotope. Because the heavier Zr isotopes exhibit energy spectra that are the more rotational, the ratios \( E(4^+_1)/E(2^+_1) \) and \( E(6^+_1)/E(2^+_1) \) are used for fixing the parameters of the Hamiltonian, while in the lighter and medium isotopes the energies of the \( 2^+_1, 2^+_2 \) and \( 0^+_2 \) states are used to fix the Hamiltonian. The fact that, in particular, for the \( 4^+_1 \) and \( 0^+_2 \) states, large deviations appear when comparing the calculated \( B(E2) \) values with the experimental data (see also Table \[1\]), points out that large contributions of configurations outside of the purely collective IBM model space are present in those states. This effect is enhanced for the low number of bosons present in the lighter isotopes. Thus, even though we cannot describe nuclear excited state properties in detail for the light Zr nuclei, what is, however, more relevant in the present study is the important change in the low-lying energy spectra when passing from mass \( A = 98 \) towards mass \( A = 100 \) that is reproduced rather well. This is also essential in deriving the binding energy effects and the \( S_{2n} \) values.

The experimental data for the different Zr isotopes have been taken from references \[23\] - \[31\]. Note that in this region, one expects the presence of intruder states but, as discussed before, those excitations are outside of the model space and are absorbed within an effective way within the changing parameters of the Hamiltonian \( \hat{H}_\text{eff} \) we are using in the present study. Therefore, the intruder states should be identified but not to be considered explicitly in the fitting procedure; this is the main difference with the technique used in Ref. \[13\], where the intruder states are considered in the fitting procedure. The more clear-cut examples, in this region, where extra configuration and thus mixing will appear are \(^{98}\text{Zr}\) and \(^{100}\text{Zr}\). In \(^{98}\text{Zr}\) the \( 0^+_2 \) state at 1.436 MeV is supposed to form the head of an intruder band \[32\]. This then could result in mixing between the \( 4^+_1 \) states resulting in pushing down the \( 4^+_1 \) state, which energy is indeed overestimated by the IBM calculation (see figure \[1\]). In the case of \(^{100}\text{Zr}\), the \( 0^+_3 \) state at 0.331 MeV is considered as an intruder state while the \( 0^+_3 \) state at 0.829 MeV is considered to be the regular state. Therefore, in figure \[1\] the \( 0^+_3 \) state that is plotted is indeed the state \( 0^+_3 \). Information on the characteristics of the excited \( 0^+_2 \) states in these nuclei is gained by studying \( E0 \) properties as discussed in detail by Wood et al. \[3\]. Note that in figure \[1\] the theoretical states for the lighter isotopes with angular momenta 6 and 8 stay out of scale, which shows again the influence of the intruder states in the lower part of the spectra. An additional problem in the description of this region arises from the low number of bosons we should use, in other words because of the proximity of the shell closure for neutrons. That creates two inconveniences, on one hand it is difficult to give a reasonable description...
for high angular momentum (note that the maximum angular momentum one can construct coupling IBM bosons is the double of the number of bosons) as observed recently in $^{96}$Sr and $^{98}$Zr nuclei [34] and, on the other hand, in the spectrum there appear non collective excitation that can only be described by a shell model calculation (see e.g. [10]).

There is a very poor knowledge of $E2$ transition rates in this mass region and so it is difficult to fix the value of parameter $\chi$ because its value it is not well defined using the information about energy spectra only. Therefore its value is fixed taking into account the information from other calculations addressing nuclei in nearby mass regions [15].

In the present calculations, we count bosons starting from a $Z = 40, N = 50$ core $^{96}$Zr which has a rather high-lying first excited state. This is at variance with recent shell-model calculations for this mass region [10] that start from a $^{88}$Sr$_{50}$ core. Since we make use of the interacting boson model approach (IBM) that does not discriminate between proton and neutron bosons, collective properties are mainly governed by the symmetry structure of the IBM Hamiltonian and the total number of bosons present. Using proton and neutron boson degrees of freedom, in a more detailed IBM-study, one needs both proton and neutron bosons to be active in order for collective deformation effects to appear. This then would imply a different choice of a closed proton core, conform with the shell-model.

The parameters of the Hamiltonian are summarized in Table I. Here, one notices that $\chi$ is fixed at the value of $-0.8$. The values of $\kappa$ are restricted to 0.032 MeV for the Zr nuclei situated in the spherical and transitional region and to 0.046 MeV for the Zr nuclei exhibiting rotational-like energy spectra in the ground band. Note the high value of $e_{d}\kappa$ in the case of $^{96}$Zr which is due to the abnormally high excitation energy of the $0^+_2$ state that is described in terms of a subshell closure at the neutron $N = 56$.

We present in Table II the comparison between the experimental and theoretical $E2$ transition rates, keeping $\chi = -0.8$ and fixing $e_{eff} = 0.159$ e b for reproducing the $B(E2; 2^+_1 \rightarrow 0^+_1)$ value in $^{100}$Zr. The agreement of the results is reasonable except for the transitions $4^+_1 \rightarrow 2^+_1$ and $0^+_2 \rightarrow 2^+_1$ in $^{94}$Zr, which suggests that those states are outside of the IBM collective space to a large extent, as is also corroborated by the shell-model calculations carried out in $^{92}$Zr [10]. The $4^+_3$ located at 2.330 MeV is a good candidate as IBM partner, while there is no other candidate for $0^+$. Once the energy spectra for the even-even Zr isotopes have been fitted, one derives the global part $S_{2n}$ assuming the equivalence,

$$S_{2n}^{gl} \equiv A + BN = S_{2n}^{exp} - S_{2n}^{lo}.$$ (8)

Note that left hand side of equation (8) can be written in terms of the atomic number, $A$, through a trivial transformation in the parameters $A$ and $B$. In practice, the right-hand side of Eq. (8) is not an exact relation but results approximately in a straight line. As a consequence the linear part is derived from a best fit to the data points, obtained when plotting the right-hand side of (8). We like to stress at this point (see also Ref. [1]) that both the results concerning relative energies (energy spectra) and the energy surfaces do not depend on the values of $A$ and $B$ as determined here.

The global part of $S_{2n}$ corresponds to the values $A = 67.4$ MeV and $B = -0.946$ MeV (using the atomic number, $A$, as variable). The comparison between the experimental data and the theoretical results, combining the global and the local part, is given in figure 2. We like to point out that the approximately flat behavior of $S_{2n}$ at $A = 100.102$ is rather well reproduced and corresponds precisely to the neutron number where the energy spectra rapidly change from spherical into deformed structures.

Extra information that can be obtained from the present IBM calculation is the energy surface as a function of the deformation parameters. This can most easily be studied using the intrinsic-frame formalism. Here, the interacting many-boson problem is solved defining a new kind of boson -dressed bosons- that is built as a linear combination of $s$ and $d$ bosons and constructing a trial wave function as a condensate of $N$ such bosons [35, 36]. The problem is solved by minimizing the expectation value of the Hamiltonian with respect to the deformation parameters, that reduces to one, $\beta$. In figure 3, we present the energy surfaces for the different Zr isotopes according to the parametrization as described in Table II. It is clearly observed that $^{94-98}$Zr remain spherical. Note that the flat energy surface of $^{94}$Zr appears due to the low number of bosons for this nucleus, $N=2$, and to the fact that the depth of the potential energy surface is proportional to $N(N-1)$. $^{100}$Zr is a special case because this nucleus appears to be situated very close to the critical region where two minima coexist [37], one spherical and one deformed. One notices that the energy surface is very flat which is caused by the fact that a deformed minimum and a spherical maximum appear that are almost degenerate. This indicates that one is close to the critical area [37]. Finally, $^{102-104}$Zr become well deformed. Recent theoretical studies using relativistic mean-field (RMF) methods [38] (concentrating on nuclear charge radii, mainly) and Hartree- Fock-Bogoliubov (HFB) methods [39] (studying the Zr isotopic chain up to the two-neutron drip line) have concentrated on shape properties and their variation from spherical towards strongly deformed Zr nuclei. In this brief report, we have studied the energy spectra and the $S_{2n}$ values for the neutron-rich even-even Zr isotopes in a consistent way using the IBM framework. The new experimental data on masses are rather well reproduced starting from a schematic calculation. From inspecting the corresponding energy surface diagrams, one clearly observes how the Zr isotopes evolve from spherical into deformed shapes passing through a region where two minima exist.
The calculations that have been carried out imply the possible presence of a phase transition, being $^{98}$Zr an almost critical nucleus. On the other hand, this mass region can also be described using configuration mixing (this will be shown elsewhere) in such a way that for $^{98}$Zr, regular and intruder states coexist very closely in energy although it should be necessary to see if the $S_{2n}$ values can be appropriately described. Both descriptions can seem equivalent, but there exist clear differences in the size of the model spaces. In the calculations carried out here, the model space only consists of states with $N$ bosons and we can follow the sequence of all states within this space as a function of boson number and a smoothly changing Hamiltonian (see Eq. 1 and Table II). On the other hand, when treating the presence of intruder states explicitly, one has to expand the configuration space such that both $N$ and $N+2$ boson configurations are considered. It might be that the occurrence of the deformed states as lowest states, forming the low-lying intruding configurations and the corresponding configuration mixing.
