THE LUMINOSITY AND MASS FUNCTIONS OF LOW–MASS STARS IN THE GALACTIC DISK: II. THE FIELD

Abstract

We report on new measurements of the luminosity function (LF) and mass function (MF) of field low–mass dwarfs derived from Sloan Digital Sky Survey (SDSS) Data Release 6 (DR6) photometry. The analysis incorporates ~ 15 million low–mass stars (0.1 M⊙ < M < 0.8 M⊙), spread over 4,800 square degrees. Stellar distances are estimated using new photometric parallax relations, constructed from ugriz photometry of nearby low–mass stars with trigonometric parallaxes. We use a technique that simultaneously measures Galactic structure and the stellar LF from 7 < M < 16. We compare the LF to previous studies and convert to a MF using the mass–luminosity relations of Delfosse et al. (2000). The system MF, measured over −1.0 < log M/M⊙ < −0.1, is well–described by a log–normal distribution with M⊙ = 0.25 M⊙. We stress that our results should not be extrapolated to other mass regimes. Our work generally agrees with prior low–mass stellar MFs and places strong constraints in future star–formation studies of the Milky Way.

Subject headings: stars: low mass — stars: fundamental parameters — stars: M dwarfs — stars: luminosity function— stars: mass function— Galaxy: structure

1. INTRODUCTION

Low–mass dwarfs (0.1 M⊙ < M < 0.8 M⊙) are, by number, the dominant stellar population of the Milky Way. These long-lived (Laughlin et al. 1997) and ubiquitous objects comprise ∼ 70% of all stars, yet their diminutive luminosities (L ≲ 0.05 L⊙) have traditionally prohibited their study in large numbers. However, in recent years, the development of large–format CCDs has enabled accurate photometric surveys over wide solid angles on the sky, such as the Two–Micron All Sky Survey (2MASS: Skrutskie et al. 2006) and the Sloan Digital Sky Survey (SDSS; York et al. 2000). These projects obtained precise (σ ≲ 5%) and deep (r ∼ 22, J ∼ 16.5) photometry of large solid angles (∼ 104 sq. deg.). The resulting photometric datasets contain millions of low–mass stars, enabling statistical investigations of their properties. In particular, 2MASS photometry led to the discovery of two new spectral classes: I and T (Kirkpatrick et al. 1999; Burgasser et al. 2002), and was used to trace the structure of the Sagittarius dwarf galaxy (Majewski et al. 2003) with M giants. SDSS data led to the discovery of the first field methane brown dwarf, which was the coolest substellar object known at the time of its discovery (Strauss et al. 1999). Other notable SDSS results include the discovery of new stellar streams in the Halo (e.g. Yanny et al. 2003; Belokurov et al. 2006) and new Milky Way companions (e.g., Willman et al. 2005; Belokurov et al. 2007), as well as unprecedented in situ mapping of the stellar density (Jurić et al. 2008) and metallicity (Ivezic et al. 2008) distributions of the Milky Way and confirmation of the dual-halo structure of the Milky Way (Carollo et al. 2007). SDSS has proven to be a valuable resource for statistical investigations of the properties of low–mass stars, including their magnetic activity and chromospheric properties (West et al. 2004, 2008), flare characteristics (Kowalski et al. 2009) and their use as tracers of Galactic structure and kinematics (Bochanski et al. 2007a; Fuchs et al. 2009).

Despite the advances made in other cool–star topics, two fundamental properties, the luminosity and mass functions, remain uncertain. The luminosity function (LF) describes the number density of stars as a function of absolute magnitude (Φ(M) = dN/dM). The mass function (MF), typically inferred from the LF, is defined as the number density per unit mass (ψ(M) = dN/dM). For low–mass stars, with lifetimes much greater than the Hubble time, the observed present-day mass function (PDMF) in the field should trace the initial mass function (IMF). Following Salpeter (1955), the IMF has usually been characterized by a power–law ψ(M) = dN/dM ∝ M−α, with the exponent α varying over a wide range, from 0.5 to 2.5. However, some studies have preferred a log–normal distribution. Present investigations are summarized in Table 1 (MF) and Table 2 (LF), which show the total number of stars included and solid angle surveyed in each study.

Present uncertainties in the LF and MF can be attributed to disparate measurement techniques that are a result of trade–offs in observing strategy. Previous investigations of the LF and MF have fallen in one of two categories: nearby, volume–limited studies of trigonometric parallax stars; or pencil–beam surveys of distant stars over a small solid angle. Tables 1 & 2 detail the techniques used by modern investigations of the field LF and MF. In both cases, sample sizes were limited to a
few thousand stars, prohibiting detailed statistical measurements. The solid angle shown in each table distinguishes the two types of surveys. There is considerable disagreement between the nearby, volume–limited investigations (Reid & Gizis 1997) and pencil beam studies of distant stars (Martini & Osmer 1998; Zheng et al. 2001; Schultheis et al. 2006). It has been suggested that this discrepancy is due to the presence of unresolved binary stars in the pencil beam surveys (Kroupa et al. 1993; Chabrier 2003b), but this has not been shown conclusively (Reid & Gizis 1997). We investigate the effect of unresolved binaries in §5.5.

Using a sample drawn from SDSS, 2MASS and Guide Star Catalog photometry, and supplemented with SDSS spectroscopy, Covey et al. (2008) performed the largest field low–mass LF and MF investigation to date. Covering 30 sq. deg. and containing ∼ 30,000 low–mass stars, their sample measured the LF using absolute magnitudes estimated from photometric colors, and quantified the contamination rate by obtaining spectra of every red point source in a 1 sq. deg. calibration region. The Covey et al. (2008) sample serves as a calibration study for the entire SDSS samples. While their study focused on a limited sightline, the current investigation expands to the entire SDSS footprint, increasing the solid angle by a factor of ∼ 300.

In §2, we describe the SDSS photometry used to measure the field LF and MF. The color–absolute magnitude calibration is discussed in §3. In §4, we introduce a new technique for measuring the LF of large, deep photometric datasets, and compare to previous analyses. The resulting “raw” LF is corrected for systematic effects such as unresolved binarity, metallicity gradients and changes in Galactic structure in §5. The final LF and our MF is presented in §6 and §7. Our conclusions follow in §8.

2. OBSERVATIONS

2.1. SDSS Photometry

The Sloan Digital Sky Survey (SDSS; York et al. 2000; Stoughton et al. 2002) employed a 2.5m telescope (Gunn et al. 2006) at Apache Point Observatory (APO) to conduct a photometric survey in the optical ugriz filters (Fukugita et al. 1996; Ivezić et al. 2007). The sky was imaged using a time-delayed integration technique. Great circles on the sky were scanned along six camera columns, each consisting of five 2048 × 2048 Site/Tektronix CCDs with an exposure time of ∼ 54 seconds (Gunn et al. 1998). A custom photometric pipeline (Photo; Lupton et al. 2001) was constructed to analyze each image and perform photometry. Calibration onto a standard star network (Smith et al. 2002) was accomplished using observations from the “Photometric Telescope” (PT; Hogg et al. 2001; Tucker et al. 2006). Further discussion of PT calibrations for low–mass stars can be found in Davenport et al. (2007). Absolute astrometric accuracy is better than 0.1′′ (Pier et al. 2003). Centered on the Northern Galactic Cap, the imaging data spans ∼ 10,000 square degrees, and is 95% complete to r ∼ 22.2 (Stoughton et al. 2002; Adelman-McCarthy et al. 2008). When the North Galactic Pole was not visible from APO, ∼ 300 sq. deg were scanned along the δ = 0 region known as “Stripe 82” to empirically quantify completeness and photometric precision (Ivezić et al. 2007). Over 357 million unique photometric objects have been identified in the latest public data release (DR7, Abazajian et al. 2009). The photometric precision of SDSS is unrivaled for a survey of this size, with typical errors < 0.02 mag (Ivezić et al. 2004, 2007).

2.2. Sample Selection

We queried the SDSS catalog archive server (CAS) through the casjobs website (O’Mullane et al. 2005) through point sources with the following criteria:

- The observations fell within the Data Release 6 - Legacy (DR6; Adelman-McCarthy et al. 2008) footprint. The equatorial and Galactic coordinate maps of the sample are shown in Figure 1.

- The photometric objects were flagged as PRIMARY. This flag serves two purposes. First, it implies that the GOOD flag has been set, where GOOD = !BRIGHT AND (!BLENDED OR NODEBLEND OR N_CHILD = 0). BRIGHT refers to duplicate detections of bright objects and the other set of flags ensures that stars were not deblended and counted twice. The PRIMARY flag indicates that objects imaged multiple times are only counted once 2°.

- The object was classified morphologically as a star. (TYPE = 6).

- The photometric objects fell within the following brightness and color limits:

  \[ i < 22.0, \quad z < 21.2 \]
  \[ r - i \geq 0.3, \quad i - z \geq 0.2 \]

The first two cuts extend past the 95% completeness limits of the survey (i < 21.3, z < 20.5; Stoughton et al. 2002), but more conservative completeness cuts are enforced below. The latter two cuts ensure that the stars have red colors typical of M dwarfs (Bochanski et al. 2007b; Covey et al. 2007; West et al. 2008).

This query produced 32,816,619 matches. To ensure complete photometry, we required 16 < r < 22. These cuts conservatively account for the bright end of SDSS photometry, since the detectors saturate near 15th magnitude (Stoughton et al. 2002). At the faint end, the r < 22 limit is slightly brighter than the formal 95% completeness limits. 23,323,453 stars remain after these brightness cuts.

SDSS provides many photometric flags that assess the quality of each measurement. These flags are described in detail by Stoughton et al. (2002) and in the SDSS web documentation. With the following series of flag cuts, the ∼ 23 million photometric objects were cleaned to a complete, accurate sample. Since only the r, i and z filters were used in this analysis, all of the following flags

6 http://casjobs.sdss.org/CasJobs/
7 Note that ! indicates the NOT logical operator.
8 http://www.astro.princeton.edu/~rhl/flags.html and http://www.sdss.org/dr7/products/catalogs/flags_detail.html provide excellent documentation of flag properties.

aSee Gliese & Jahreiss (1991) for details on sources of photometry.
bThe 8 pc sample was further extended by Reid et al. (1999) and Reid et al. (2003) and presented in $J$ by Cruz et al. (2007).
cSome of the HST observations in this study were presented by Gould et al. (1996) and Gould et al. (1997).
were only applied to those filters. The \( r \)–band distribution of sources is shown in Figure 2, along with the subset eliminated by each flag cut described below. The color–color diagrams for each of these subsets are shown in Figure 3.

Saturated photometry was removed by selecting against objects with the SATURATED flag set. As seen in Figure 2, this cut removes mostly objects with \( r < 15 \). However, there were some fainter stars within the footprint of bright, saturated stars. These stars are also marked as SATURATED and not included in our sample. NOTCHECKED was used to further clean saturated stars from the photometry. This flag marks areas on the sky where Photo did not search for local maxima, such as the cores of saturated stars. Similarly, we eliminated sources with PEAKCENTER set, where the center of a photometric object is identified by the peak pixel, and not a more sophisticated centroiding algorithm. As seen in Figure 2, both of these flags composed a small fraction of the total number of observations and are more common near the bright and faint ends of the photometry. Saturated objects and very low signal-to-noise observations will fail many of these tests.

The last set of flags examines the structure of the PSF after it has been measured. The PSF\_FLUX\_INTERP flag is set when over 20% of the star’s PSF is interpolated. While Stoughton et al. (2002) claim that this procedure generally provides trustworthy photometry, they warn of cases where this may not be true. Visual inspection of the \( r - i, i - z \) color–color diagram in Figure 3 confirmed the latter, showing a wider locus than other flag cuts. The INTERP\_CENTER flag is set when a pixel within three pixels of the center of a star is interpolated. The \( r - i, i - z \) color–color diagram of objects with INTERP\_CENTER set is also wide and the fit to the PSF could be significantly affected by an interpolated pixel near its center (Stoughton et al. 2002).

Thus, stars with these flags set were removed. Finally, BAD\_COUNTS\_ERROR is set when a significant fraction of the star’s PSF is interpolated over and the photometric error estimates should not be trusted. Table 3 lists the number of stars in the sample with each flag set. For the final “clean” sample, we defined the following metaflag:

\[
\text{clean} = \left( \text{SATURATED}_{r,i,z} \text{ AND } \text{PEAKCENTER}_{r,i,z} \text{ AND } \text{NOTCHECKED}_{r,i,z} \text{ AND } \text{PSF\_FLUX\_INTERP}_{r,i,z} \text{ AND } \text{INTERP\_CENTER}_{r,i,z} \text{ AND } \text{BAD\_COUNTS\_ERROR}_{r,i,z} \text{ AND } (16 < \text{psfMag}_r < 22) \right)
\]

After the flag cuts the stellar sample was composed of 21,418,445 stars.

The final cut applied to the stellar sample was based on distance. As explained below in §4.1, stellar densities were calculated within a \( 4 \times 4 \times 4 \) kpc\(^3\) cube centered on the Sun. Thus, only stars within this volume were retained, and the final number of stars in the sample is 15,340,771\(^9\).

In Figure 4, histograms of the \( r - i, i - z \) and \( r - z \) colors are shown. These color histograms map directly to absolute magnitude, since color–magnitude relations (CMRs) are used to estimate absolute magnitude and distance. The structure seen in the color histograms at \( r - i \sim 1.5 \) and \( r - z \sim 2.2 \) results from the convolution of the peak of the LF with the Galactic stellar density profile over the volume probed by SDSS. Removing the density gradients and normalizing by the volume sampled constitutes the majority of the effort needed to convert these color histograms into a LF. The \( (g - r, r - i) \) and \( (r - i, i - z) \) color–color diagrams are shown in Figure 5, along with the model predictions of Baraffe et al. (1998) and Girardi et al. (2004). It is clearly evident that the models fail to reproduce the stellar locus, with discrepancies as large as \( \sim 1 \) mag. These models should not be employed as color–absolute-magnitude relations for low–mass stars.

2.3. Star–Galaxy Separation

With any deep photometric survey, accurate star–galaxy separation is a requisite for many astronomical investigations. At faint magnitudes, galaxies far outnumber stars, especially at the Galactic latitudes covered by SDSS. Star–galaxy identification is done automatically in the SDSS pipeline, based on the brightness and morphology of a given source. Lupton et al. (2001) investigated the fidelity of this process, using overlap between HST observations and early SDSS photometry. They showed that star–galaxy separation is accurate for more than 95% of objects to a magnitude limit of \( r \sim 21.5 \). Since the present sample extends to \( r = 22 \), we re-investigated the star–galaxy separation efficiency of the SDSS pipeline. We matched the SDSS pipeline photometry to the Hubble Space Telescope ACS images within the COSMOS (Scoville et al. 2007) footprint. The details of this analysis will be published in a later paper (Bochanski et al., 2010, in prep). In Figure 6, we plot the colors and brightnesses of COSMOS galaxies identified as stars by the SDSS pipeline (red filled circles), along with a representative subsample of 0.02% of the stars in our sample. This figure demonstrates that for the majority of the stars in the present analysis, the SDSS morphological indentifications are adequate and contamination by galaxies is not a major systematic.

---

\(^9\) The reported number is based on the \( (M_r, r - z) \) color–magnitude relation (CMR). As explained in §5, changes to the CMR can add or subtract stars from the volume.
3. CALIBRATION: PHOTO METRIC PARALLAX

Accurate absolute magnitude estimates are necessary to measure the stellar field LF. Trigonometric parallaxes, such as those measured by Hipparcos (ESA 1997; van Leeuwen 2007), offer the most direct method for calculating absolute magnitude. Unfortunately, trigonom etric parallaxes are not available for many faint stars, including the overwhelming majority of the low–mass dwarfs observed by SDSS. Thus, other methods must be employed to estimate a star’s absolute magnitude (and distance). Two common techniques, known as photometric parallax and spectroscopic parallax, use a star’s color or spectral type, respectively. These methods are calibrated by sources with known absolute magnitudes (nearby trigonometric parallax stars, clusters, etc.) and mathematical relations are fit to their color (or spectral type) – absolute magnitude locus. Thus, the color of a star can be used to estimate its absolute magnitude, and in turn, its distance, by the well-known distance modulus (\(m - M\)):

\[
m_{\lambda,1} - M_{\lambda,1}(m_{\lambda,1} - m_{\lambda,2}) = 5\log d - 5 \tag{1}
\]

where \(d\) is the distance, \(m_{\lambda,1}\) is the apparent magnitude in one filter, and \(m_{\lambda,1} - m_{\lambda,2}\) is the color from two filters, which is used to calculate the absolute magnitude, \(M_{\lambda,1}\).

There have been multiple photometric parallax relations\(^{10}\), as shown in Figure 7, constructed for low–mass stars observed by SDSS (Hawley et al. 2002; Williams et al. 2002; West et al. 2005; Jurić et al. 2008; Sesar et al. 2008; Golimowski et al. 2010). There is a spread among the relations, seen in Figure 8, which are valid over different color ranges. Additional photometry in \(ugrizJHK_s\) of a large sample of nearby stars with well–measured trigonometric parallaxes is required to provide a reliable relation. Fortunately, an observing program led by Golimowski et al. (2010) acquired such observations and they kindly provided their data prior to publication. The resulting CMRs are used to estimate the absolute magnitude and distance to all the stars in our sample, as described below.

3.1. Photometric Telescope Photometry

The nearby star survey (Golimowski et al. 2010) targeted stars with the colors of low–mass dwarfs and precise trigonometric parallaxes. The majority of targets were drawn from the Research Consortium on Nearby Stars (RECONS) catalog (e.g., Henry et al. 1994; Kirkpatrick et al. 1995; Henry et al. 2004). Most of the stars

\[^{10}\] Photometric parallax relations are often referred to as “color–magnitude relations” (CMRs). We use both names interchangeably throughout this manuscript.
selected from the RECONS sample are within 10 pc, with good parallactic precision ($\sigma/\pi < 0.1$). In addition to RECONS targets, the nearby sample included K dwarfs from the Luyten (1979) and Giclas et al. (1971) proper motion surveys. Parallax measurements for these additional stars were obtained from the Hipparcos (ESA 1997) or General Catalogue of Trigonometric Stellar Parallaxes (the “Yale” catalog; van Altena et al. 1995) surveys.

Near-infrared $JHK_s$ photometry was obtained from the 2MASS Point Source Catalog (Cutri et al. 2003). Acquiring $ugriz$ photometry proved more problematic. Since typical SDSS photometry saturates near $r \sim 15$, most of the nearby stars were too bright to be directly imaged with the 2.5m telescope. Instead, the 0.5m Photometric Telescope (PT) was used to obtain ($ugriz$)′ photometry\(^{11}\) of these stars. The PT was active every night the 2.5m telescope was used in imaging mode during the SDSS, observing patches of the nightly footprint to determine the photometric solution for the night and to calibrate the zero-point of the 2.5m observations (Smith et al. 2002; Tucker et al. 2006). Golimowski et al. (2010) obtained ($ugriz$)′ photometry of the parallax sample over 20 nights for 268 low–mass stars. The transformations of Tucker et al. (2006) and the Davenport port et al. (2007) corrections were applied to the nearby star photometry to transform the “primed” PT photometry to the native “unprimed” 2.5m system (see Davenport et al. (2007) for more details).

To produce a reliable photometric parallax relation, the following criteria were imposed on the sample, First, stars with large photometric errors ($\sigma > 0.1$ mags) in the $griz$ bands were removed. Next, high signal–to–noise 2MASS photometry was selected, by choosing stars with their pflag equal flag equal to ‘AAA’. This flag corresponds to a signal–to–noise ratio > 10 and photometric uncertainties < 0.1 mags in the $JHK_s$ bands. Next, a limit on parallactic accuracy of $\sigma/\pi < 0.10$ was enforced. It ensured that the bias introduced by a parallax–limited sample, described by Lutz & Kelker (1973), is minimized. Since many of the stars in the nearby star sample have precise parallaxes ($\sigma/\pi < 0.04$), the Lutz-Kelker correction is essentially negligible ($< -0.05$; Hanson 1979). Finally, contaminants such as known subdwarfs, known binaries, suspected flares, or white dwarfs were culled from the nearby star sample.

3.2. Additional Photometry

To augment the original PT observations, we searched the literature for other low–mass stars with accurate parallaxes and $ugriz$ and $JHK_s$ photometry. The studies of Dahn et al. (2002) and Vrba et al. (2004) supplemented the original sample and provided accurate parallaxes ($\sigma/\pi < 0.1$) of late M and L dwarfs. Several of those stars were observed with the SDSS 2.5m telescope, obviating the need for transformations between the primed and unprimed $ugriz$ systems. Six late M and L dwarfs were added from these catalogs, extending the parallax sample in color from $r - i \sim 2.5$ to $r - i \sim 3.0$ and in $M_r$ from 16 to 20. Our final sample is given in Bochanski (2008).

3.3. Color Magnitude Relations

Multiple color–absolute magnitude diagrams (CMDs) in the $ugriz$ and $JHK_s$ bandpasses were constructed using the photometry and parallaxes described above. The CMDs were individually inspected, fitting the main sequence with linear, 2nd, 3rd, and 4th–order polynomials. Piecewise functions were also tested, placing discontinuities by eye along the main sequence. There is extensive discussion in the literature of a “break” in the main sequence near spectral type M4 (or $V - I \sim 2.8$, see Hawley et al. 1996; Reid & Gizis 1997; Reid & Cruz 2002; Reid & Hawley 2005). Certain colors, such as $V - I$ show evidence of a break (Fig. 10 of Reid & Cruz 2002), while other colors, such as $V - K_s$ do not (Fig. 9 of Reid & Cruz 2002). We did not enforce a break in our fits. Finally, the rms scatter about the fit for each CMD was computed and the relation that produced the smallest scatter for each color–absolute magnitude combination was retained. Note that the rms scatter was dominated by the intrinsic width of the main sequence, as both our photometry and distances have small ($\sim 2\%$) uncertainties.

We present three different CMRs: $(M_r, r - i)$, $(M_r, r - z)$ and $(M_r, i - z)$ in Table 4. $M_r$ was used for absolute magnitude, as it contains significant flux in all late-type stars. The $r - z$ color has the longest wavelength baseline and small residual rms scatter ($\sigma < 0.40$ mag). Other long baseline colors ($g - r, g - z$) are metallicity sensitive (West et al. 2004; Lépine & Scholz 2008) but most of our sample does not have reliable $g$–band photometry. The adopted photometric parallax relations in these colors did not include any discontinuities, although we note a slight increase in the dispersion of the main sequence around $M_r \sim 12$. The final fits are shown in Figures 7, 9.
Fig. 4.— Histograms of color for the final stellar sample in $r - i$ and $r - z$.

Fig. 5.— Color-color diagrams of the final photometric sample with the 5 Gyr isochrones of Baraffe et al. (1998, red dashed line) and Girardi et al. (2004, yellow dashed line) overplotted. The contours represent 0.2% of our entire sample, with contours increasing every 10 stars per 0.05 color-color bin. Note that the model predictions fail by nearly one magnitude in some locations of the stellar locus.

Fig. 6.— The Hess diagram for objects identified as stars in the SDSS pipeline, but as galaxies with high-resolution ACS imaging in the COSMOS footprint (red filled circles). The black points show 0.02% of the final stellar sample used in the present analysis. Note that galaxy contamination is the most significant at faint, blue colors. These colors and magnitudes are not probed by our analysis, since these objects lie beyond our $4 \times 4 \times 4$ kpc distance cut.

and 10, along with other published photometric parallax relations in the $ugriz$ system.

4. Analysis

Our photometric sample comprises a data-set three orders of magnitude larger (in number) than any previous LF study (see Table 2). Furthermore, it is spread over 8,400 sq. deg., nearly 300 times larger than the sample analyzed by Covey et al. (2008). This large sky coverage represents the main challenge in measuring the LF from this sample. Most of the previous studies in Table 2 either assumed a uniform density distribution (for nearby stars) or calculated a Galactic density profile, $\rho(r)$ along one line of sight. With millions of stars spread over nearly 1/4 of the sky, numerically integrating Galactic density profiles for each star is computationally prohibitive.

To address this issue, we introduced the following technique for measuring the luminosity function. First, absolute magnitudes were assigned and distances to each star were computed using the $r - z$ and $r - i$ CMRs from Table 4. Each CMR was processed separately. Next, a small range in absolute magnitude (0.5 mag) was selected and
the stellar density was measured \textit{in situ} as a function of Galactic radius ($R$) and Galactic height ($Z$). This range in absolute magnitude was selected to provide high resolution in the LF, while maintaining a large number of stars ($\sim 10^6$) in each bin. Finally, a Galactic profile was fit to the $R,Z$ density maps, solving for the shape of the thin and thick disks, as well as the local density. The LF was then constructed by combining the local density of each absolute magnitude slice.

### 4.1. Stellar Density Maps

To assemble a ($R,Z$) density map, an accurate count of the number of stars in a given $R,Z$ bin, as well as the volume spanned by each bin, was required. A cylindrical ($R,Z,\phi$) coordinate system was taken as the natural coordinates of stellar density in the Milky Way. In this frame, the Sun’s position was set at $R_\odot = 8.5$ kpc (Kerr & Lynden-Bell 1986) and $Z_\odot = 15$ pc above the Plane (Cohen 1995; Ng et al. 1997; Binney et al. 1997). Azimuthal symmetry was assumed (and was recently verified by Jurić et al. (2008) and found to be appropriate for the local Galaxy). The following analysis was carried out in $R$ and $Z$. We stress that we are not presenting any information on $\phi = 0$ plane. Rather, the density maps are summed over $\phi$, collapsing the three-dimensional SDSS volume into a two–dimensional density map.

The coordinate transformation from a spherical coordinate system ($\ell, b, d$) to a cylindrical ($R, Z$) system was performed with the following equations:

\begin{equation}
R = \sqrt{(d \cos b)^2 + R_\odot (R_\odot - 2d \cos b \cos \ell)}
\end{equation}

\begin{equation}
Z = Z_\odot + d \sin(b - \arctan(Z_\odot/R_\odot))
\end{equation}

where $d$ was the distance (as determined by Equation 1 and the ($M_\ell, r - z$) CMR), $\ell$ and $b$ are Galactic longitude and latitude, respectively, and $R_\odot$ and $Z_\odot$ are the

![Fig. 7.— $M_\ell$ vs. $r - i$ CMD. The parallax stars from the nearby star sample are shown as filled circles and the best fit line from Table 4 is the solid red line. Other existing parallax relations are plotted for comparison: West et al. (2005, purple dash-dot line), Jurić et al. (2008, their “bright” relation; green dash-dot line), Sesar et al. (2008, yellow dash-dot line), Golimowski et al. (2010, solid blue line). The original West et al. (2005) relations have been transformed using the data from their Table 1. In addition, the 5 Gyr isochrone from the Baraffe et al. (1998) models appears as the dashed line.

![Fig. 8.— Differences between the $M_\ell$ vs. $r - i$ relations in Figure 7. The line styles are the same as Figure 7. Note that the observed photometric parallax relations generally agree to $\sim 0.5$ mags, while the 5 Gyr isochrone of Baraffe et al. (1998) does not agree with the empirical results.]

| Abs. Mag. | Color range | Best Fit | $\sigma_{M_\ell}$ |
|-----------|-------------|----------|------------------|
| $M_\ell$  | $0.50 < r - z < 4.53$ | $5.190 + 2.474 (r - z) + 0.4340 (r - z)^2 - 0.08635 (r - z)^3$ | 0.394 |
| $M_\ell$  | $0.62 < r - i < 2.82$ | $5.025 - 4.548 (r - i) + 0.1475 (r - i)^2 - 0.18315 (r - i)^3$ | 0.403 |
| $M_\ell$  | $0.32 < i - z < 1.85$ | $4.748 + 8.275 (i - z) + 2.2789 (i - z)^2 - 1.5337 (i - z)^3$ | 0.481 |

position of the Sun, as explained above\textsuperscript{12}. The density maps were binned in $R$ and $Z$. The bin width needed to be large enough to contain many stars (to minimize Poisson noise), but small enough to accurately resolve the structure of the thin and thick disks. The $R, Z$ bin size was set at 25 pc. An example of the star counts as a function of $R$ and $Z$ is shown in Figure 11.

\textsuperscript{12}Note that Eqn. (3) should contain a term with $\ell$. We ignore this term due to its small size relative to the $d \sin b$ term.
After calculating the volume of each $R, Z$ bin, the density (in units of stars pc$^{-3}$) is simply:

$$\rho(R, Z) = \frac{N(R, Z)}{V(R, Z)}$$  \hfill (4)

with the error given by:

$$\sigma_\rho = \rho \sqrt{\left(\frac{\sqrt{N(R, Z)}}{N(R, Z)}\right)^2 + \left(\frac{k\sqrt{N_{\text{points}}(R, Z)}}{V(R, Z)}\right)^2}$$  \hfill (5)

where $N(R, Z)$ is the star counts in each $R, Z$ bin and $V(R, Z)$ is the corresponding volume. Fiducial density and error maps are shown in Figures 13 and 14. Note that the error in Eqn. 5 is dominated by the first term on the right hand side. While a smaller $k$ could make the second term less significant, it would be computationally prohibitive to include more test points. We discuss systematic errors which may influence the measured density in §5.

4.2. Galactic Model Fits

Using the method described above, $(R, Z)$ stellar density maps were constructed for each 0.5 mag slice in $M_r$, from $M_r = 7.25$ to $M_r = 15.75$, roughly corresponding to spectral types M0-M8. The bin size in each map was constant, at 25 pc in the $R$ and $Z$ directions. For $R, Z$ bins with density errors (Equation 5) of $<15\%$, the following disk density structure was fit:

$$\rho_{\text{thin}}(R, Z) = \rho_0 f e^{-\frac{R-R_{0, \text{thin}}}{\sigma_{R, \text{thin}}}} e^{-\frac{|Z|-Z_{0, \text{thin}}}{\sigma_{Z, \text{thin}}}}$$  \hfill (6)

$$\rho_{\text{thick}}(R, Z) = \rho_0 (1-f) e^{-\frac{R-R_{0, \text{thick}}}{\sigma_{R, \text{thick}}}} e^{-\frac{|Z|-Z_{0, \text{thick}}}{\sigma_{Z, \text{thick}}}}$$  \hfill (7)

$$\rho(R, Z) = \rho_{\text{thin}}(R, Z) + \rho_{\text{thick}}(R, Z)$$  \hfill (8)

where $\rho_0$ is the local density at the solar position ($R_0 = 8500$ pc; $Z_0 = 15$ pc), $f$ is the fraction of the local density contributed by the thin disk, $R_{0, \text{thin}}$ and $R_{0, \text{thick}}$ are the thin and thick disk scale lengths, and $Z_{0, \text{thin}}$ and $Z_{0, \text{thick}}$ are the thin and thick disk scale heights, respectively. Since the density maps are dominated by nearby disk structure, the halo was neglected. Furthermore, Jurić et al. (2008) demonstrated that the halo structure is only important at $|Z| > 3$ kpc, well outside the volumes probed here. Restricting the sample to bins with density errors $<15\%$ ensures that they are well-populated by stars and have precise volume measurements, and should accurately trace the underlying Milky Way stellar distri-
distribution. Approximately 50% of the $R, Z$ bins have errors $\geq 15\%$, while containing $> 90\%$ of the stars in the sample.

The density maps were fit using Equation 8 and a standard Levenberg–Marquardt algorithm (Press et al. 1992), using the following approach. First, the thin and thick disk scale heights and lengths, and their relative scaling, were measured using ten absolute magnitude slices, from $M_r = 7.25 - 11.75$. These relatively more luminous stars yield the best estimates for Galactic structure parameters. Including lower-luminosity stars biases the fits, artificially shrinking the scale heights and lengths to compensate for density differences between a small number of adjacent $R, Z$ bins. The scale lengths and heights and their relative normalization were fit for the entire $M_r = 7.25 - 11.75$ range simultaneously. The resulting Galactic structure parameters ($Z_o, \sigma$, $R_o$, $Z_o, \sigma$, $f$) are listed in Table 5 as raw values, not yet corrected for systematic effects (see §5 and Table 6). After the relative thin/thick normalization ($f$) and the scale heights and lengths of each component are fixed, the local densities were fit for each absolute magnitude slice, using a progressive sigma clipping method similar to that of Jurić et al. (2008). This clipping technique excludes obvious density anomalies from biasing the final best-fit. First, a density model was computed, and the standard deviation ($\sigma$) of the residuals was calculated. The $R, Z$ density maps were refit and bins with density residuals greater than 50σ are excluded. This process was repeated multiple times, with $\sigma$ smoothly decreasing by the following series: $\sigma = (40, 30, 20, 10, 5)$. An example luminosity function, constructed from the local densities of each absolute magnitude slice and derived from the $M_R, r - z$ CMR, is shown in Figure 15.

The observed LF is subject to systematics imposed by nature, such as unresolved binarity and metallicity gradients, as well as those from the observations and analysis, e.g. Malmquist bias. The systematic differences manifested in different CMRs, which vary according to stellar metallicity, interstellar extinction, and color, are isolated and discussed in §5.1 and §5.2, and the results are used in §5.3 to estimate the systematic uncertainties in the LF and Galactic structure.

Malmquist bias (§5.4) and unresolved binarity (§5.5) were quantified using Monte Carlo (MC) models. Each model was populated with synthetic stars that were consistent with the observed Galactic structure and LF. The mock stellar catalog was analyzed with the same pipeline as the actual observations and the differences between the input and “observed” Galactic structure and LF were used to correct the observed values.

5.1. Systematic CMRs: Metallicity

A star with low metallicity will have a higher luminosity and temperature compared to its solar–metallicity counterpart of the same mass, as first described by Sandage & Eggen (1959). However, at a fixed color, stars with lower metallicities have fainter absolute magnitudes. Failing to account for this effect artificially brightens low-metallicity stars, increasing their estimated distance. This inflates densities at large distances, increasing the observed scale heights (e.g., King et al. 1990).

Quantifying the effects of metallicity on low-mass dwarfs is complicated by multiple factors. First, direct metallicity measurements of these cool stars are difficult (e.g., Woof & Wallerstein 2006; Johnson & Apps 2009), as current models do not accurately reproduce their complex spectral features. Currently, measurements of metallicity-sensitive molecular bandheads (CaH and TiO) are used to estimate the metallicity of M dwarfs at the $\sim 1$ dex level (see Gizis 1997; Lépine et al. 2003; Burgasser & Kirkpatrick 2006; West et al. 2008), but detailed measurements are only available for a few stars. The effects of metallicity on the absolute magnitudes of low–mass stars are poorly constrained. Accurate parallaxes for nearby subdwarfs do exist (Monet et al. 1992; Reid 1997; Burgasser et al. 2008), but measurements of their precise metal abundances are difficult given the extreme complexity of calculating the opacity of the molecular absorption bands that dominate the spectra of M dwarfs. Observations of clusters with known metallicities could mitigate this problem (Clem et al. 2008; An et al. 2008), but there are no comprehensive observations in the ugriz system that probe the lower main sequence.

To test the systematic effects of metallicity on this

![Fig. 15.— The raw $r$-band LF for the stellar sample, using the $(M_r, r - z)$ CMR. Note the smooth behavior, with a peak near $M_r \sim 11$, corresponding to a spectral type of $\sim$ M4. The error bars (many of which are smaller than the points) are the formal uncertainties from fitting the local densities in each 0.5 mag absolute magnitude slice in stellar density.](image-url)
study, the \((Fe/H), \Delta M_r\) relation from Ivezić et al. (2008) was adopted. We note that this relation is appropriate for more luminous F and G stars, near the main-sequence turnoff, but should give us a rough estimate for the magnitude offset. The adopted Galactic metallicity gradient is:

\[
[Fe/H] = -0.0958 - 2.77 \times 10^{-4} |Z| \quad \text{(9)}
\]

At small Galactic heights \((Z \lesssim 100 \text{ pc})\), this linear gradient produces a metallicity of about \([Fe/H] = -0.1\), appropriate for nearby, local stars (Allende Prieto et al. 2004). At a height of \(\sim 2 \text{ kpc}\) (the maximum height probed by this study), the metallicity is \([Fe/H] \sim -0.65\), consistent with measured distributions (Ivezić et al. 2008). The actual metallicity distribution is probably more complex, but given the uncertainties associated with the effects of metallicity on M dwarfs, adopting a more complex description is not justified. The correction to the absolute magnitude, \(\Delta M_r\), measured from F and G stars in clusters of known metallicity and distance (Ivezić et al. 2008), is given by:

\[
\Delta M_r = -0.10920 - 1.11[Fe/H] - 0.18[Fe/H]^2 \quad \text{(10)}
\]

Substituting Equation 9 into Equation 10, yields a quadratic equation for \(\Delta M_r\) in Galactic height. After initially assigning absolute magnitudes and distances with the CMRs appropriate for nearby stars, each star’s estimated height above the Plane, \(Z_{\text{ini}}\), was computed. This is related to the star’s actual height, \(Z_{\text{true}}\), through the following equation:

\[
Z_{\text{true}} = Z_{\text{ini}} + \frac{\Delta M_r}{\Delta M_r(z_{\text{ini}})} \quad \text{(11)}
\]

A star’s true height above the Plane was calculated by finding the root of this non-linear equation. Since \(\Delta M_r\) is a positive value, the actual distance from the Galactic plane, \(Z_{\text{true}}\), is smaller than the initial estimate, \(Z_{\text{ini}}\). As explained above, this effect becomes important at larger distances, moving stars inwards and decreasing the density gradient. Thus, if metallicity effects are neglected, the scale heights and lengths are overestimated.

In Figure 16, the systematic effects of metallicity dependent CMRs are shown. The first is the extreme limit, shown as the red histogram, where all stars in the sample have an \([Fe/H] \sim -0.65\), corresponding to a \(\Delta M_r\) of roughly 0.5 magnitudes. All of the stars in the sample are shifted to smaller distances, greatly enhancing the local density. This limit is probably not realistic, as prior luminosity function studies (e.g., Reid & Gizis 1997; Cruz et al. 2007) would have demonstrated similar behavior. The effect of the metallicity gradient given in Equation 9 is shown with the solid blue line. Note that local densities are increased, since more stars are shifted to smaller distances.

5.2. Systematic CMRs: Extinction

The extinction and reddening corrections applied to SDSS photometry are derived from the Schlegel et al. (1998) dust maps and an assumed dust law of \(R_V = 3.1\) (Cardelli et al. 1989). The median extinction in the sample is \(A_r = 0.09\), while 95% of the sample has \(A_r < 0.41\). Typical absolute magnitude differences due to reddening range up to \(\sim 1\) magnitude, producing distance corrections of \(\sim 40\) pc, enough to move stars between adjacent \(R, Z\) bins and absolute magnitude bins. This effect introduces strong covariances between adjacent luminosity bins, and implies that the final LF depends on the assumed extinction law. Most of the stars in our sample lie beyond the local dust column, and the full correction is probably appropriate (Marshall et al. 2006). To bracket the effects of extinction on our analysis, two LFs were computed. The first is the \((M_r, r-z)\) LF, which employs the entire extinction correction. The second uses the same CMR, but without correcting for extinction. The two LFs are compared in Figure 17. When the extinction correction is neglected, stellar distances are underestimated, which increases the local density. This effect is most pronounced for larger luminosities. The dominant effect in this case is not the attenuation of light due to extinction, but rather the reddening of stars, which causes the stellar absolute magnitudes to be underestimated.

5.3. Systematic Uncertainties

The statistical error in a given LF bin is quite small, typically \(\lesssim 0.1\%\), and does not represent a major source of uncertainty in this analysis. The assumed CMR dominates the systematic uncertainty, affecting the shape of the LF and resulting MF. To quantify the systematic uncertainty in the LF and Galactic structure, the following procedure was employed. The LF was computed five times using different CMRs: The \((M_r, r - z)\) and \((M_r, r - i)\) CMRs with and without metallicity corrections, and the \((M_r, r - z)\) CMR without correcting for Galactic extinction. The LFs measured by each CMR are plotted in Figure 18, along with the unweighted mean of the five LF determinations. The uncertainty in a given LF mag bin was set by the maximum and minimum of the five test cases, often resulting in asymmetric error bars. This uncertainty was propagated through the entire analysis pipeline using three LFs: the mean, the “maximum” LF, corresponding to the maximum \(\Phi\) in each magnitude bin.
When no extinction correction is applied (open squares), distant stars act to inflate the local densities of the brightest stars, compared to the fiducial case (filled circles). At fainter luminosities, this effect becomes less important.

The “minimum” LF, corresponding to the lowest $\Phi$ value. We adopted the mean LF as the observed system LF and proceeded to correct it for the effects of Malmquist bias and binarity, as described below.

Fig. 17.— The systematic effect of extinction on the raw LF. When no extinction correction is applied (open squares), distant stars act to inflate the local densities of the brightest stars, compared to the fiducial case (filled circles). At fainter luminosities, this effect becomes less important.

The mean observed system LF, derived from five Monte Carlo Models: Malmquist Bias

Malmquist bias effects were quantified by including dispersions in absolute magnitude of $\sigma_{r-z} = 0.5$ mag and a color dispersion of $\sigma_{r-i} = 0.05$ mag. These values were chosen to be somewhat closer to the observed scatter in the color–magnitude diagrams (see Table 4). The LF measured with the Malmquist bias model is shown in Figure 19. The correction is important for most of the stars in the sample, especially the brightest stars ($M_r < 10$). Stars at this magnitude and color ($r-i \sim 0.5, r-z \sim 1$, see Figure 4) are very common in the SDSS sample because they span a larger volume than lower luminosity stars. Thus, they are more susceptible to having over-luminous stars scattered into their absolute magnitude bins. However, the dominant factor that produced the differences between the raw and corrected LFs was the value of the thin disk scale height.

5.5. Monte Carlo Models: Unresolved Binarity

For all but the widest pairs, binaries in our sample will masquerade as a single star. The unresolved duo will be over-luminous at a given color, leading to an underestimate of its distance. This compresses the density maps, leading to decreased scale heights and lengths, as binary systems are assigned smaller distances appropriate to single stars.

Currently, the parameter space that describes M dwarf binaries: binary fraction, mass ratio, and average separation, is not well constrained. However, there are general trends that are useful for modeling their gross properties. First, the binary fraction ($f_b$) seems to steadily decline from $\sim 50\%$ at F and G stars (Duquennoy & Mayor 1991) to about $30\%$ for M dwarfs (Fischer & Marcy 1992; Delfosse et al. 2004; Lada 2006; Burgasser et al. 2007). Next, the mass ratio distribution becomes increasingly peaked towards unity at lower masses. That is, F and G stars are more likely to have a companion from a wide range of masses, while M dwarfs are commonly found with a companion of nearly the same mass, when the M dwarf is the primary (warmer) star (Burgasser et al. 2007). The average separation distribution is not well known, but many companions are found with separations of $\sim 10 - 30$ AU (Fischer & Marcy 1992), while very low mass stars have smaller average separations (Burgasser et al. 2007). At the typical distances probed by the SDSS sample (100s of pc) these binary systems would be unresolved by SDSS imaging with an average PSF width of $1.4''$ in $r$. 

5.4. Monte Carlo Models: Malmquist Bias

Malmquist bias (Malmquist 1936) arises in flux-limited surveys (such as SDSS), when distant stars with brighter absolute magnitudes (either intrinsically, from the width of the main sequence, or artificially, due to measurement error) scatter into the survey volume. These stars have their absolute magnitudes systematically overestimated (i.e., they are assigned fainter absolute magnitudes than they actually possess), which leads to underestimated intrinsic luminosities. Thus, their distances will be systematically underestimated. This effect artificially shrinks the observed scale heights, and inflates the measured LF densities. Assuming a Gaussian distribution about a “true” mean absolute magnitude $M_0$, classical Malmquist bias is given by:

$$M(m) = M_0 - \frac{\sigma^2}{\log e} \frac{dA(m)}{dn}$$

where $\sigma$ is the spread in the main sequence (or CMR), $dA(m)/dn$ is the slope of the star counts as a function of apparent magnitude $m$, and $M(m)$ is the observed mean absolute magnitude. Qualitatively, $M(m)$ is always less than $M_0$ (assuming $dA(m)/dn$ is positive), meaning that the observed absolute magnitude distribution is skewed towards more luminous objects.

Monte Carlo models were used to quantify the effects of Malmquist bias by including dispersions in absolute magnitude of $\sigma_{r-z} = 0.3$ and $\sigma_{r-i} = 0.5$ mag and a color dispersion of $\sigma_{r-i} = 0.05$ mag. These values were chosen to reflect the observed scatter in the color–magnitude diagrams (see Table 4). The LF measured with the Monte Carlo model is shown in Figure 19. The correction is important for most of the stars in the sample, especially the brightest stars ($M_r < 10$). Stars at this magnitude and color ($r-i \sim 0.5, r-z \sim 1$, see Figure 4) are very common in the SDSS sample because they span a larger volume than lower luminosity stars. Thus, they are more susceptible to having over-luminous stars scattered into their absolute magnitude bins. However, the dominant factor that produced the differences between the raw and corrected LFs was the value of the thin disk scale height.

Fig. 18.— The mean observed system LF, derived from five different CMRs. Each CMR is described in the legend. The uncertainty in a given LF bin is set by the full range spanned by the five different LFs.
We introduced binaries into our simulations with four different binary fraction prescriptions. The first three ($f_b = 30\%, 40\%$ and $50\%$) are independent of primary star mass. The fourth binary fraction follows the methodology of Covey et al. (2008) and is a primary–star mass–dependent binary fraction, given by:

$$f_b(M_p) = 0.45 - \frac{0.7 - M_p}{4}$$

where $M_p$ is the mass of the primary star, estimated using the Delfosse et al. (2000) mass–luminosity relations. This linear equation reflects the crude observational properties described above for stars with $M_p < 0.7 M_\odot$. Near $1 M_\odot$, the binary fraction is $\sim 50\%$, while at smaller masses, the binary fraction falls to $\sim 30\%$. Secondary stars are forced to be less massive than their primaries. This is the only constraint on the mass–ratio distribution.

An iterative process, similar to that described in Covey et al. (2008), is employed to estimate the binary–star population. First, the mean observed LF from Figure 18 is input as a primary–star LF (PSLF). A mock stellar catalog is drawn from the PSLF, and binary stars are generated with the prescriptions described above. Next, the flux from each pair is merged, and new colors and brightnesses are calculated for each system. Scatter is introduced in color and absolute magnitude, as described in §5.4. The stellar catalog is analyzed with the same pipeline as the data, and the output model LF is compared to the observed LF. The input PSLF is then tweaked according to the differences between the observed system LF and the model system LF. This loop is repeated until the artificial system LF matches the observed system LF. Note that the Galactic structure parameters are also adjusted during this process, and the bias–corrected values are given in Table 6. The thin disk scale height, which has a strong effect on the derived LF, is in very good agreement with previous values. As the measured thin disk scale height increases, the density gradients decrease, and a smaller local density is needed to explain distant structures. This change is most pronounced at the bright end, where the majority of the stars are many thin disk scale heights away from the Sun (see Figure 19). The preferred model thin disk and thick disk scale lengths were found to be similar. This is most likely due to the limited radial extent of the survey compared to their typical scale lengths. Upcoming IR surveys of disk stars, such as APOGEE (Allende Prieto et al. 2008), should provide more accurate estimates of these parameters.

SDSS observations form a sensitive probe of the thin disk and thick disk scale heights, since the survey focused mainly on the Northern Galactic Cap. Our estimates suggest a larger thick disk scale height and smaller thick disk fraction than recent studies (e.g., Siegel et al. 2002; Jurić et al. 2008). However, these two parameters are highly degenerate (see Figure 1 of Siegel et al. 2002). In particular, the differences between our investigation and the Jurić et al. (2008) study highlight the sensitivity of these parameters to the assumed CMR and density profiles, as they included a halo in their study and we did not. The Jurić et al. (2008) study sampled larger distances than our work, which may affect the resulting Galactic parameters. However, the smaller normalization found in our study is in agreement with recent results from a kinematic analysis of nearby M dwarfs with SDSS spectroscopy (Pineda et al. 2010). They find a relative normalization of $\sim 5\%$, similar to the present investigation. The discrepancy in scale height highlights the need for additional investigations into the thick disk and suggests that future investigations should be presented in terms of stellar mass contained in the thick disk, not scale height and normalization.

The iterative process described above accounts for binary stars in the sample, and allows us to compare the system LF and single–star LF in Figure 20. Most observed LFs are system LFs, except for the local volume–limited surveys. However, most theoretical investigations into the IMF predict the form of the single star MF. Note that for all binary prescriptions, the largest differences between the two LFs are seen at the faintest $M_r$, since the lowest luminosity stars are most easily hidden in binary systems.

**Fig. 19.** The effects of Malmquist bias (orange and blue filled circles), unresolved binarity (black) and Galactic structure (GS) on the survey. The mean observed LF is larger than the corrected LF at most bins. The largest effects are seen for the brightest stars, which are subject to the largest shifts due to a change in the thin disk scale height. The difference between the orange and blue LFs demonstrate the sensitivity of the Malmquist correction to the assumed scatter in the main sequence. The binary correction becomes relatively more important at fainter absolute magnitudes. The LF from Jurić et al. (2008, open squares) is shown for comparison to our raw system LF. They did not probe faint absolute magnitudes, employed a different CMR, and did not correct their densities for Malmquist bias, which accounts for the offsets between their LF and ours.

6. RESULTS: LUMINOSITY FUNCTION

The final adopted system and single star $M_r$ LFs are presented in Figure 21. The LFs were corrected for unresolved binarity and Malmquist bias. The uncertainty in each bin is computed from the spread due to CMR differences, binary prescriptions and Malmquist corrections. The mean LFs and uncertainties are listed in Tables 7 and 8. The differences between the single and system LFs are discussed below and compared to previous studies in both $M_r$ and $M_J$. 
6.1. Single–Star vs. System Luminosity Function

Figure 21 demonstrates a clear difference between the single–star LF and the system LF. The single–star LF rises above the system LF near the peak at \( M_r \sim 11 \) (or a spectral type \( \sim M4 \)), and maintains a density about twice that of the system LF\(^\text{13}\). This implies that lower luminosity stars are easily hidden in binary systems, but isolated low–luminosity systems are intrinsically rare. The agreement between the system and single–star LFs at high luminosities is a byproduct of our binary prescription, which enforced that a secondary be less massive than its primary–star counterpart. Since our LF does not extend to higher masses (G and K stars), we may be missing some secondary companions to these stars, which would inflate the single–star LF at high luminosities. However, only \( \sim 700,000 \) G dwarfs are present in the volume probed by this study. Even if all of these stars harbored an M–dwarf binary companion, the resulting differences in a given bin would be only a fraction of a percent.

6.2. \( M_r \) LF

Since many traditional LF studies have not employed the \( r \)–band, our ability to compare to previous results is hampered. The most extensive study of the \( M_r \) LF was conducted by Jurić et al. (2008), using 48 million photometric SDSS observations, over different color ranges. Figure 19 compares the \( M_r \) system LF determined here to the “joint fit, bright parallax” results of Jurić et al. (2008, their Table 3), assuming 10\% error bars. The two raw system LFs broadly agree statistically, although the Jurić et al. (2008) work only probes to \( M_r \sim 11 \), due to their red limit of \( r – i \sim 1.4 \). We compare system LFs, since the Jurić et al. (2008) study did not explicitly compute a SSLF and their reported LF was not corrected for Malmquist bias.

6.3. \( M_J \) LF

We next converted \( M_r \) to \( M_J \) using relations derived from the calibration sample described in Bochanski (2008). The \( J \) filter has traditionally been used as a tracer of mass (Delfosse et al. 2000) and bolometric luminosity (Golimowski et al. 2004) in low–mass stars, since it samples the SED near its peak. The largest field LF investigation to date, Covey et al. (2008), determined the \( J \) band LF from \( M_J = 4 \) to \( M_J = 12 \). In Figure 22, our transformed system \( M_J \) LF (given in Table 9) is plotted with the \( M_J \) LF from Covey et al. (2008). The shape of these two LFs agree quite well, both peaking near \( M_J = 8 \), although there appears to be a systematic offset, in that our \( M_J \) LF is consistently lower than the one from the Covey et al. (2008) study. This is most likely due to the different CMRs employed by the two studies. Covey et al. (2008) used an \( (M_I, i – J) \) CMR, as opposed to the various CMRs employed in the current study.

\(^\text{13}\) We note that the differences between our system and single–star LFs disagree considerably with those reported by Covey et al. (2008). These differences were investigated, and the Covey et al. (2008) binary corrections were found to be erroneous, with companion stars sampled from the MF convolved with the full sample volume, which is inappropriate for companion stars. The authors regret the error.

Note. — Densities are reported in units of (stars pc$^{-3}$ 0.5 mag$^{-1}$) $\times 10^{-3}$.

Figure 22 also compares our single star $M_J$ LF to the LF of primaries and secondaries first measured by Reid & Gizis (1997) and updated by Cruz et al. (2007). These stars are drawn from a volume–complete sample with $d < 8$ pc. A total of 146 stars in 103 systems are found within this limit. The distances for the stars in this volume–complete sample are primarily found from trigonometric parallaxes, with < 5% of the stellar distances estimated by spectral type. There is reasonable agreement between our $M_J$ LF and the LF from the volume–complete sample, within the estimated uncertainties, indicating that the photometric and volume–complete methods now give similar results. Furthermore, it indicates that our assumed CMRs are valid for local, low–mass stars. Finally, the agreement between the single–star LFs validates our assumed corrections for unresolved binarity.

7. RESULTS: MASS FUNCTION

The mass function (MF) was calculated from the $M_J$ LFs and the mass–luminosity ($M_J$) relation from Delfosse et al. (2000). We computed both a single star MF and system MF. As discussed in Covey et al. (2008), some past discrepancies between MFs are probably due to comparing analytic fits and the actual MF data. This effect is discussed below, where we compare our results to available MF data from nearby (e.g., Reid & Gizis 1997) and distant (e.g., Zheng et al. 2001) samples. We also compare our analytic fits to seminal IMF studies.

The single star and system MFs are shown in Figure 23. As seen in the LFs, there is agreement between the two relations at higher masses. At masses less than 0.5 $M_\odot$, the shapes of the MFs are roughly equivalent, but the single star density is roughly twice that of the systems. We note a small possible correction to the lowest mass bin ($\log M/M_\odot = -0.95$). At these masses, young brown dwarfs, with ages less than 1 Gyr and masses near $M \sim 0.075 M_\odot$ will have luminosities similar to late–type M dwarfs. Since these objects are not stellar, they should be removed from our mass function. Assuming a constant star formation rate, Chabrier (2003a) estimated that brown dwarfs contribute ~ 10% of the observed densities at the faintest absolute magnitudes (or lowest
masses). Recent studies of nearby, young M dwarfs (e.g., Shkolnik et al. 2009) show that \(~ 10\%\) have ages less than 300 Myr, further supporting the presence of young brown dwarfs in our sample. Thus, a correction of 10\% to the lowest mass bin would account for young brown dwarfs (see Figure 23). We don’t apply the correction, but include its impact on the uncertainty of the last MF bin.

In Figures 24 and 25 we display the log–normal and broken power law fits to the system and single star MFs. While the broken power law is preferred by many observers (Covey et al. 2008; Kroupa 2002), the log–normal formalism has been popularized by some theorists (e.g., Hennebelle & Chabrier 2008). Our MF data are best fit by a log–normal distribution, as confirmed by an f test. We suggest using the log–normal form when comparing to previous MF fits, but stress that comparisons using the actual MF data (Tables 11 and 12) are preferred.

The system MF is compared to the pencil beam survey of Zheng et al. (2001) MF in Figure 24. Their data were acquired with the Hubble Space Telescope, and the stars in their sample are at distances similar to this study. The Zheng et al. (2001) study sparked some discussion in the literature (e.g., Chabrier 2003a,b), as their results differed dramatically from the nearby star sample (e.g., Reid & Gizis 1997). The proposed solution was unresolved binarity. Binary systems would be resolved easily at small distances, but not at the larger distances probed by the HST sample. We compare our system MF to the Zheng et al. (2001) sample, and find agreement over a large range of masses (\(M < 0.4M_\odot\)). At larger masses (\(M \sim 0.4M_\odot\)), the MFs diverge. This can most likely be attributed to differing CMRs, in particular differences in the corrections for stellar metallicity gradients.

Our single star MF is compared to the nearby star sample (Reid & Gizis 1997) in Figure 25. The MFs agree remarkably well, with discrepancies in only two bins (likely the result of small numbers in the nearby star sample). This indicates that our CMRs and methodology are valid, since the output densities are in agreement. It suggests that our binary corrections are reasonable, as both our system and single star MFs agree with previous results. Moreover, the discrepancy between the Reid & Gizis (1997) and Zheng et al. (2001) MFs can be attributed to unresolved binarity. The Reid & Gizis (1997) MF results present a single–star MF, while the Zheng et al. (2001) MF is a system MF.

We compare our single–star LF to semianal IMF analytic fits in Figure 26 (see Table 1). While we advocate the comparison of MF data whenever possible (as discussed in Covey et al. 2008), it is informative to compare our results to these studies. The Kroupa (2002) and Chabrier (2003a) studies demonstrate the best agreement with our data at masses \(M < 0.4M_\odot\), but diverge at higher masses, predicting larger space densities than we infer here. The disagreement of the Miller & Scalo (1979) MF with the other three MFs suggest an issue with their normalization.

### 7.1. The IMF in other Mass Regimes

A single analytic description of the IMF over a wide range in mass may not be appropriate. Figure 27 shows the derived mass functions from this study, and those from the Reid & Gizis (1997) sample and the Pleiades

| -0.65           | 7.21            | 8.53            | 5.89            |
| -0.75           | 5.38            | 6.29            | 4.47            |
| -0.85           | 4.79            | 5.45            | 4.14            |
| -0.95           | 5.11            | 6.42            | 3.41            |

**Note.** — Densities are reported in units of (stars pc\(^{-3}\) 0.1 log \(M^{-1}\)) \times 10^{-3}.
Fig. 23.— The single star MF (red filled circles) and system MF (open squares) for this study. Note that the largest differences between the two MFs occur at smaller masses, since low–mass stars are easily obscured in binary systems with a higher mass primary. The possible correction for young brown dwarfs discussed in §7 is shown as an open circle in the single–star MF.

Fig. 24.— The system MF (filled circles), along with broken power law (dashed line) and log–normal (dot–dashed line) fits. The power law break occurs near 0.3 $M_\odot$. The parameters of both fits are found in Table 13. The MF data (open squares) and power law fit from Zheng et al. (2001, light dashed line) are also shown. The agreement between our data and the Zheng et al. (2001) data is good at lower masses, but the data diverge at higher masses.

Fig. 25.— The single star MF (filled circles). We fit this distribution with a broken power law (dashed line) and a log–normal distribution (dot–dashed line). The parameters of these fits are found in Table 14. The MF data (open squares) and single power law fit from Reid & Gizis (1997, light dashed line) are also shown. The data are in reasonable agreement, with discrepancies larger than the error bars in only two bins.

Fig. 26.— Shown is the MF data and best log-normal fit from this study (solid circles and red line), along with the analytic MF fits of Chabrier (2003a, green dashed line), Kroupa (2002, dark blue dash–dot–dot–dot line) and Miller & Scalo (1979, light blue dash-dot line). We stress that comparing actual MF data is more valid than comparing analytic fits.

Note. — Densities are reported in units of (stars pc$^{-3}$ 0.1 log M$^{-1}$) $\times$10$^{-3}$.

19.7. Theoretical Implications of the IMF

Any successful model of star formation must accurately predict the IMF. The measured field MF traces the IMF of low–mass stars averaged over the star formation history of the Milky Way. Thus, the field MF is not a useful tool for investigating changes in the IMF due to
from our study systematically under–predicts the density at masses the gas, with properties tied to the shock properties. Multiple shocks produce filaments within shocks compress the molecular gas (Larson 1981; Padoan et al. 2001). Multiple shocks produce filaments within Taurus (Luhman 2004a, 2006) or Chamaeleon (Joergens 2006). Turbulence readily produces a clump distribution similar to the ubiquitous Salpeter IMF at high masses (> 1 $M_\odot$). However, the flattening at lower masses is reproduced if only a fraction of clumps are dense enough to form stars (Moraux et al. 2007). An alternative model to turbulent fragmentation is accretion and ejection (Bate & Bonnell 2005). Briefly, small cores form near the opacity limit (∼ 0.003 $M_\odot$), which is set by cloud composition, density and temperature. These clumps proceed to accrete nearby gas. Massive stars form near the center of the cloud’s gravitational potential, thus having access to a larger gas reservoir. Accretion ends when the nascent gas is consumed or the accreting object is ejected via dynamical interactions. The characteristic mass is set by the accretion rate and the typical time scale for ejection, with more dense star forming environments producing more low–mass stars. This method has fallen out of favor recently, as brown dwarfs have been identified in weakly bound binaries (Luhman 2004b; Luhman et al. 2009), which should be destroyed if ejection is a dominant mechanism. Furthermore, if ejection is important, the spatial density of brown dwarfs should be higher near the outskirts of a cluster compared to stars, and this is not observed in Taurus (Luhman 2004a, 2006) or Chamaeleon (Joergens 2006).

Larson (2005) suggested that thermal cooling arguments are also important in star formation. This argument has gained some popularity, as it predicts a relative insensitivity of the IMF to initial conditions, which is supported by many observations (e.g., Kroupa 2002; Moraux et al. 2007; Bastian et al. 2010, and references therein) have mainly focused on three major mechanisms that would shape the low–mass IMF: turbulent fragmentation, competitive accretion & ejection, and thermal cooling arguments. Turbulent fragmentation occurs when supersonic shocks compress the molecular gas (Larson 1981; Padoan et al. 2001). Multiple shocks produce filaments within the gas, with properties tied to the shock properties.

**TABLE 13**

**SYSTEM Mass Function Analytic Fits**

| Form                  | Mass Range       | Parameter     |
|-----------------------|------------------|---------------|
| Log–Normal            | $-1.0 < \log M/M_\odot < -0.1$ | $C_0 = 0.008 \pm 0.001$ $M_\odot = 0.25 \pm 0.01$ $\sigma = 0.28 \pm 0.02$ |
| Broken Power Law (Low–Mass) | $0.1 \ M_\odot < M < 0.32 \ M_\odot$ | $\alpha = 0.35 \pm 0.07$ |
| Broken Power Law (High–Mass) | $0.32 \ M_\odot < M < 0.8 \ M_\odot$ | $\alpha = 2.38 \pm 0.05$ |

**TABLE 14**

**Single Mass Function Analytic Fits**

| Form                  | Mass Range       | Parameter     |
|-----------------------|------------------|---------------|
| Log–Normal            | $-1.0 < \log M/M_\odot < -0.1$ | $C_0 = 0.011 \pm 0.002$ $M_\odot = 0.18 \pm 0.02$ $\sigma = 0.34 \pm 0.05$ |
| Broken Power Law (Low–Mass) | $0.1 \ M_\odot < M < 0.32 \ M_\odot$ | $\alpha = 0.98 \pm 0.15$ |
| Broken Power Law (High–Mass) | $0.32 \ M_\odot < M < 0.8 \ M_\odot$ | $\alpha = 2.66 \pm 0.10$ |

Note: We use the form $\psi(M) = C_0 e^{\left(\log M - \log M_\odot\right)^2/2\sigma^2}$ for the log–normal fit and $\psi(M) \propto M^{-\alpha}$ for the power law fit.

![Fig. 27.](image)

**Fig. 27.** Shown is the single star MF and best log normal fit from this study (red filled circles and solid line), the Reid & Gizis (1997, open squares) MF (open squares) and the Pleiades MF Moraux et al. (2004, green triangles, ). The best fit extrapolated from our study systematically under–predicts the density at masses outside the bounds of our data.

Clumps then form along these filaments and collapse ensues. In general, the shape of the IMF depends on the Mach number and power spectrum of shock velocities (Ballesteros-Paredes et al. 2006; Goodwin et al. 2006) and the molecular cloud density (Padoan & Nordlund 2002). Turbulence readily produces a clump distribution similar to the ubiquitous Salpeter IMF at high masses (> 1 $M_\odot$). However, the flattening at lower masses is reproduced if only a fraction of clumps are dense enough to form stars (Moraux et al. 2007).
This insensitivity is due to changes in the cooling rate with density. At low densities, cooling is controlled by atomic and molecular transitions, while at higher densities, the gas is coupled with dust grains, and these dust grains dominate the cooling. The result is an equation of state with cooling at low densities and a slight heating term at high densities. This equation of state serves as a funneling mechanism and imprint a characteristic mass on the star formation process, with little sensitivity to the initial conditions.

The general shape of the IMF has been predicted by star formation theories that account for all of these effects (Chabrier 2003a, 2005). In particular, the high mass IMF is regulated by the power spectrum of the turbulent flows (Hennebelle & Chabrier 2009) and is probably affected by the coagulation of less massive cores, while the flatter, low–mass distribution can be linked to the dispersions in gas density and temperatures (Moraux et al. 2007; Bonnell et al. 2006). As the IMF reported in this study is an average over the star formation history of the Milky Way, changes in the characteristic shape of the IMF cannot be recovered. However, our observational IMF can rule out star formation theories that do not show a flattening at low masses, with a characteristic mass \( \sim 0.2 M_\odot \). Recent numerical simulations have shown favorable agreement with our results (Bate 2009), however most numerical simulations of star formation are restricted in sample size and suffer significant Poisson uncertainties. Analytical investigations of the IMF (Hennebelle & Chabrier 2008) are also showing promising results, reproducing characteristic masses \( \sim 0.3 M_\odot \) and log–normal distributions in the low–mass regime.

8. CONCLUSIONS

We have assembled the largest set of photometric observations of M dwarfs to date and used it to study the low–mass stellar luminosity and mass functions. Previous studies were limited by sample size, mostly due to the intrinsic faintness of M dwarfs. The precise photometry of the SDSS allowed us to produce a clean, complete sample of M dwarfs, nearly two orders of magnitude larger than other studies.

To accurately estimate the brightness and distances to these stars, we constructed new photometric parallax relations from data kindly provided to us prior to publication (Golimowski et al. 2010). These relations were derived from \( ugrizJHK_s \) photometry of nearby stars with known trigonometric parallax measurements. We compared our new relations to those previously published for SDSS observations.

We also introduced a method for measuring the LF within large surveys. Previous LF investigations either assumed a Galactic profile (for pencil beam surveys, such as Zheng et al. 2001) or a constant density (for nearby stars, i.e. Reid & Gizis 1997). However, none of these samples have approached the solid angle or number of the stars observed in this study. We solved for the LF and Galactic structure simultaneously, using a technique similar to Jurić et al. (2008). Our LF is measured in the \( r \)-band. Using multiple CMRs, we investigated systematic errors in the LF, and computed the effects of Malmquist bias, unresolved binarity and Galactic structure changes using Monte Carlo models. This allowed us to compare our results both to distant LF studies (which sampled mostly the system LF) and nearby star samples (which can resolve single stars in binary systems).

Finally, we computed mass functions for single stars and systems. Low luminosity stars are more common in the single star MF, since they can be companions to any higher mass star. We fitted both MFs with a broken power law, a form preferred by Kroupa (2001), and a log–normal distribution, which is favored by Chabrier (2003a). The log–normal distribution at low masses seems to be ubiquitous: it is evident both in the field (this study; Chabrier 2003a) and open clusters, such as Blanco 1 (Moraux et al. 2007), the Pleiades (Moraux et al. 2004), and NGC 6611 (Oliveira et al. 2009). The best fits for this study are reported in Tables 13 and 14 . We stress the point first made in Covey et al. (2008), that comparing MF data is preferable to comparing analytic fits, since the latter are often heavily swayed by slight discrepancies amongst the data. We also caution the reader against extrapolating our reported mass function beyond \( 0.1 \, M_\odot < M < 0.8 \, M_\odot \), the masses that bound our sample. In the future, we plan to investigate the luminosity function in other SDSS bandpasses, such as \( i \) and \( z \). Our system and single-star MFs represent the best current values for this important quantity for low–mass stars.

JJB would like to acknowledge the support of the UW Astronomy department over the course of his thesis study. In particular, he would like to acknowledge Ivan King, Andrew Becker, Nick Cowan, Lucianne Walkowicz, Nathan Kaib and Richard Plotkin for fruitful and helpful discussions. He also acknowledges the support and guidance of Adam Burgasser. We also thank the anonymous referee, whose insightful comments, especially on star–galaxy separation, greatly strengthened this paper. We also gratefully acknowledge the support of NSF grants AST 02-05875 and AST 06-07644 and NASA ADP grant NAG5-13111. We appreciate the serene and productive atmosphere fostered by Friday Harbor Labs, where this project first started.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England.
