Abstract

**Background:** Proximal humeral fractures can progress to osteonecrosis of the humeral head. Hertel developed a binary classification system (12 subtypes) and demonstrated that pattern types 2, 9, 10, 11, and 12, or fracture extension of the posteromedial head less than or equal to 8 mm, or diaphysis deviation greater than 2 mm, are at greater risk for osteonecrosis. Few studies have evaluated the incidence of osteonecrosis after proximal humerus fractures were treated using osteosynthesis through the anterolateral approach. The objectives of this study were to correlate osteonecrosis predictors established by the Hertel classification with the risk for developing osteonecrosis and its incidence after osteosynthesis using the anterolateral approach.

**Methods:** This was a retrospective study of patients who underwent osteosynthesis of proximal humerus fractures using an anterolateral approach. Patients were divided into two groups: high risk for necrosis (group 1) and low risk for necrosis (group 2) according to Hertel's criteria. The overall prevalence of osteonecrosis and the prevalences in each group were calculated. A radiological examination was performed in the anteroposterior, scapular, and axillary views, before and after the operation (minimum 1 year after surgery). The groups were compared using the Chi-square test or Fisher's exact test. The unpaired t-test (parametric variables) and the Mann-Whitney test (non-parametric) were used.

**Results:** In total, 39 patients were evaluated. The postoperative follow-up time was 14.5 ± 3.3 months. Time to onset of necrosis was 14.1 ± 3.9 months. Sex, age, and time between trauma and surgery did not influence the risk of necrosis. Type 2, 9, 10, 11, and 12, or fractures with posteromedial head extension less than or equal to 8 mm, or diaphysis deviation greater than 2 mm, as well as grouping did not influence the risk for osteonecrosis.

**Conclusions:** Hertel’s criteria were not able to predict the development of osteonecrosis after osteosynthesis of proximal humerus fractures performed through the anterolateral approach. The total prevalence of osteonecrosis was 17.9%.

1. **Introduction**

Proximal humeral fractures can progress to humeral head osteonecrosis (HHO) as a result of blood supply interruption caused by trauma (1). Anterior humeral circumflex artery is often damaged by trauma, so the posterior humeral circumflex artery is of great importance in maintaining vascularization of the humeral head (2). Many factors contribute to HHO following trauma (3, 4). Fracture characteristics including comminution, involvement of the articular surfaces, and bone fragments in the posteromedial humerus, may increase the risk of HHO (5).

The risk of HHO is an important factor in surgical decision-making. Fractures with a high risk of necrosis (especially in the elderly) can be treated with arthroplasty. In contrast, young patients and/or low-risk fractures may be treated with osteosynthesis (6). Several authors have investigated fracture patterns and correlated them with the risk of HHO. In 1971, Neer observed that four-part fractures were associated with
a greater risk of necrosis (7). More recently, Hertel developed a binary classification system (12 subtypes) and demonstrated that patterns 2, 9, 10, 11, and 12, and fractures with posteromedial head extension less than or equal to 8 mm, or diaphysis deviation greater than 2 mm (injury to the medial hinge), were at increased risk for HHO (8).

It remains controversial whether the Hertel classification can predict HHO risk (9). In Hertel’s study, humeral head perfusion was assessed intraoperatively through the deltopectoral approach (8).

Osteosynthesis for proximal humerus fractures can be performed using either a deltopectoral or anterolateral approach. Both require muscle dissection and retraction for adequate lateral humerus exposure (1, 10).

Few studies have evaluated the prevalence of HHO following osteosynthesis of proximal humerus fractures through the anterolateral approach.

2. Objectives

The primary objective of the study was to correlate osteonecrosis predictors, established by the Hertel classification, with the presence or absence of HHO following osteosynthesis of the proximal humerus through the anterolateral approach. The secondary objective was to assess the prevalence of HHO after at least 1 year of postoperative follow-up.

3. Materials And Methods

This was a retrospective study of patients who underwent osteosynthesis for proximal humerus fractures via the anterolateral approach between 2016 and 2019. Patients were included if they underwent fracture osteosynthesis via the anterolateral approach and had all the radiological images required for preoperative Hertel classification and for HHO evaluation.

Cases without complete documentation, fractures associated with a dislocation, and pathological fractures were excluded.

The Hertel classification was used to classify fractures and stratify the risk of osteonecrosis. Radiographs were taken in anteroposterior, scapular, and axillary views. Preoperative investigations were evaluated by two examiners and the kappa test was used to assess agreement between examiners. The Hertel classification was used to divide the patients into two groups. Binary patterns 2, 9, 10, 11, and 12, or posteromedial head extension less than or equal to 8 mm, or diaphysis deviation greater than 2 mm (injury to the medial hinge), were allocated to group 1 (high risk for osteonecrosis). Fractures with binary patterns 1, 3, 4, 5, 6, 7, and 8, and/or posteromedial head extension greater than 8 mm, or diaphysis deviation less than 2 mm (medial hinge integrity) were allocated to group 2 (low risk for necrosis).
Radiographic evaluations were performed using the Sinapse® digital radiography program. Postoperative radiological examinations were performed at least 1 year after the surgical procedure. Osteonecrosis was identified by a radiologist.

Patients underwent surgery in a beach chair position. A 10-cm incision was made from the anterolateral edge of the acromion in a distal direction and parallel to the axis of the diaphysis. The anterior and middle portions of the deltoid were separated by blunt dissection and the axillary nerve was identified. After fracture reduction and fixation, a provisional plate with Kirschner wires (Humerus Gm-Reis®) was placed on the lateral face of the humerus below the anterior branch of the axillary nerve.

The total prevalence of HHO and the prevalences in each group were calculated. Comparisons between groups were performed using the Chi-square or Fisher’s exact tests. Non-categorical variables were tested for normality using the Kolmogorov-Smirnov test. The unpaired t-test (parametric variables) and the Mann-Whitney test (non-parametric) were also used. A Kaplan-Meier curve was used to assess the pattern of the temporal evolution of osteonecrosis. All analyzes were performed using the PASW statistics 27.0 software (IBM Corp., Armonk, NY, USA) adopting a significance level of 5%.

The research protocol was approved by the local ethics committee (Campinas State University ethics committe – registration number 34384120.5.0000.540). All methods were analysed by this committee and were carried out in accordance with relevant guidelines and regulations. The informed consent was obtained from all patients.

All data generated and analysed during the current study are included in this published article and in the supplementary information file.

4. Results

In total, 39 patients met the inclusion criteria, with a predominance of females (55.3%). The average age was 58.4 ± 12.0 years.

On average, patients underwent surgery 6 days after the trauma. Postoperative follow-up time was 14.5 ± 3.3 months. Table 1 lists demographic data.
Table 1
Demographic data

| Variable                                    | Value         |
|---------------------------------------------|---------------|
| Age [average ± SD] (years)                  | 58.4 ± 12.0   |
| Sex [number (%)]                            |               |
| Female                                      | 22 (56.4%)    |
| Male                                        | 17 (43.6%)    |
| Trauma-to-surgery days (average ± SD)       | 6.6 ± 4.4     |
| Follow up [average ± SD] (days)             | 14.5 ± 3.4    |

In terms of agreement between observers, the lowest level was reached for the fracture extension criterion for the medial region of the head smaller than 8 mm, while high levels of agreement were reached for medial hinge loss and binary classification. To assess the risk for necrosis, the patients were grouped as high- and low-risk.

After grouping, agreement between the observers increased. Table 2 lists the Kappa data.

Table 2
Interobserver kappa test for the Hertel classification

| Hertel's criteria               | Kappa | P value |
|---------------------------------|-------|---------|
| Medial extension\(^{(a)}\)      | 0.04  | 0.60    |
| Medial hinge loss               | 0.79  | < 0.001 |
| Binary classification           | 0.62  | < 0.001 |
| High-risk group\(^{(b)}\)       | 0.89  | < 0.001 |

Progression to HHO occurred in 7 (17.9%) patients. The mean time to onset of necrosis was 14.1 ± 3.9 months (range: 3–18 months). Two patients developed humeral head necrosis (Figure 1) without collapse, while 5 patients had a collapse. Screw migration due to necrosis occurred in 3 patients and the synthesis material had to be removed.

The Kaplan Meier curve showed a tendency toward an increased incidence of HHO after 1 year of surgical treatment (Figure 2).

We evaluated associations between factors including sex, age, trauma energy, and time elapsed after fracture with HHO and found no significant associations (Table 3). The most common binary classification was the type 12 pattern (Table 4). Binary patterns and additional Hertel criteria influenced the development of HHO (Tables 4 and 5).
### Table 3
Correlations between variables and osteonecrosis

| Variable                                      | Presence of osteonecrosis | Absence of osteonecrosis | P value |

(a) Fisher’s exact test; (n) total number of patients

On the basis of the factors that could increase risk for HHO, we divided the sample into two groups. However, the groups did not differ in terms of HHO development (Table 6). Three cases had 3 risk factors for osteonecrosis and none of them developed this complication.

Table 6
Development of osteonecrosis in the two groups

| Group          | Presence of osteonecrosis (n/%) | Absence of osteonecrosis (n/%) | P value(a) |
|----------------|---------------------------------|--------------------------------|------------|
| Group 1        | 5 (12.8%)                       | 19 (48.7%)                     | 0.68       |
| Group 2        | 2 (5.1%)                        | 13 (33.3%)                     |            |
| Total          | 7 (17.9%)                       | 32 (82.1%)                     |            |

5. Discussion

Humeral head osteonecrosis is one of the most frequent complications following osteosynthesis of proximal humerus fractures (11). In this study, we observed a prevalence of 17.9%, similar to that reported by Greiner et al., who evaluated a similar cohort (12). The incidence of HHO after osteosynthesis ranges from 4–30% (11).
In terms of demographic characteristics, we observed a higher prevalence of fractures in females and the elderly, which is in agreement with the literature (13). We did not find any influence of sex and age on the development of HHO (11).

The time duration between trauma and surgery was longer in patients who developed HHO. However, it did not influence the development of osteonecrosis, which is also in agreement with the literature (12). Despite some controversy, most clinicians agree that the posterior circumflex artery provides the main arterial supply to the proximal end of the humerus after a fracture (2). It is possible that preservation of the posterior circumflex artery reduces the risk of HHO, and that the time duration between the trauma and the surgery does not influence the biological viability of the humeral head.

Some authors have investigated and classified fracture patterns. Hertel developed a classification system with criteria to predict HHO risk (8). We found a high concordance of the Hertel classification (except for the posteromedial head extension criterion less than or equal to 8 mm) between observers, as described in the literature (14).

Despite the high level of agreement in terms of the Hertel classification and criteria between observers, the system was not able to predict the risk for HHO. Even after grouping the factors, there was no difference in the incidence of HHO between the groups. Our hypothesis for the divergence from the Hertel classification is that dissections lateral to the humeral head interfere less with medial vascularization, which could reduce the risk of HHO despite the loss of the medial hinge and fragments extending to a head smaller than 8 mm.

Campochiaro et al. observed that Hertel’s criteria were not sufficient to determine the risk for developing osteonecrosis, which is similar to our findings (9). However, some studies have demonstrated that factors including medial hinge loss could increase the risk of osteonecrosis.

Most studies have assessed HHO in patients who underwent osteosynthesis through a deltopectoral approach (11, 15). The question of whether the surgical approach (deltpectoral or anterolateral) is related to the development of HHO remains controversial (16). A few studies have explored the incidence of HHO after the post-anterolateral approach (17). A systematic review by Cochrane was not able to determine whether the approach (deltpectoral or anterolateral) could influence the development of HHO because of the small number of studies related to the anterolateral approach (6). Another difficulty is that most studies evaluating the anterolateral approach have used the minimally invasive plate osteosynthesis technique (18). Therefore, to our knowledge, this is the first study to correlate the Hertel classification with risk of HHO after osteosynthesis performed through the anterolateral approach.

The main limitation of the study was the retrospective design, which did not allow comparisons with controls. However, the minimum follow-up period of 1 year after surgery, and the uniform performance of the anterolateral approach, strengthen our findings.

6. Conclusion
Hertel’s criteria were not able to predict the risk for HHO after osteosynthesis of proximal humeral fractures performed through the anterolateral approach. The overall prevalence of HHO was 17.9%.
