ABSTRACT
GaN nanowires have been grown by molecular beam epitaxy either catalyst-free or catalyst-induced by means of Ni seeds. Under identical growth conditions of temperature and V/III ratio, both types of GaN nanowires are of wurtzite structure elongated in the Ga-polar direction and are constricted by M-plane facets. However, the catalyst-induced nanowires contain many more basal-plane stacking faults and their photoluminescence is weaker. These differences can be explained as effects of the catalyst Ni seeds.

KEYWORDS
Nanowire, nanocolumn, molecular beam epitaxy (MBE), photoluminescence, stacking faults, catalyst

1. Introduction
Semiconductor nanowires (NWs) hold great promise as building blocks for novel devices in various areas like electronics, optoelectronics, photovoltaics, piezoelectronics, and thermoelectrics [1]. A major advantage of semiconductor NWs is that these nanoscale structures can be fabricated by fairly simple means involving self-organization effects only. Probably the most popular way is the vapor–liquid–solid (VLS) process [2], in which catalyst seeds, frequently tiny Au droplets, induce the formation of NWs. Recently, the vapor–solid–solid (VSS) process during which the catalyst remains solid was also evidenced to efficiently promote NW growth [3, 4]. Although widespread, the use of a catalyst raises the question whether some of the seed material is incorporated into the NWs [5–7] and adversely affects their properties, thus preventing high-performance applications. Hence, there are increasing efforts to grow NWs without any metal catalyst being used [8–13]. While significant efforts have been directed at detecting contamination by the catalyst material, so far little attention has been paid to possible differences in the quality of the products of the two approaches to fabricate NWs. For the case of GaN NWs grown by molecular beam epitaxy (MBE) with similar growth windows (V/III ratio and temperature), the formation can be either catalyst-induced...
[14] by a VSS mechanism [15] or catalyst-free [16, 17] depending on the type of substrate.

Here, we make use of this unique possibility to directly compare the structural and optical properties of NWs grown by both pathways under otherwise identical conditions in order to deduce the effect of the catalyst on the material quality. We find major differences that imply significant negative consequences if catalyst seeds are employed to synthesize semiconductor nanowires for use in devices.

2. Experimental

GaN NWs were grown on C-plane sapphire, Si(111), and on Si(001) substrates by plasma-assisted MBE under nitrogen-rich (N-rich) conditions. For the catalyst-induced pathway, Ni islands resulting from annealing of a 4 Å thin layer were used as seeds [14]. For the catalyst-free pathway, the samples were grown on Si substrates cleaned with the RCA procedure. GaN was grown on each substrate for the same duration under identical conditions, i.e., a $V/\text{III}$ ratio of 5 and a substrate temperature of 780 °C. The morphology of the NWs was investigated by scanning electron microscopy (SEM) as described in Ref. [14]. In order to assess the NW crystal structure, specimens were prepared either by NW harvesting from the substrate or by the standard mechanical thinning and ion milling processes for cross-sectional transmission electron microscopy (TEM). The optical properties of the as-grown NW samples were investigated with a photoluminescence (PL) set-up equipped with a Cryovac microscope cryostat. For excitation, we used the 325 nm line of a Kimmon He–Cd laser focused to a micrometer-sized spot by a 15× microscope objective. The PL signal was collected by the same objective, and analyzed by a 0.8 m Jobin-Yvon monochromator equipped with a cooled Si charge-coupled-device (CCD) detector.

3. Results and discussion

3.1 Morphology

All the samples were entirely covered by NWs oriented perpendicularly to the substrate as seen in the SEM images in Fig. 1. On sapphire substrates the NWs formed only in the presence of Ni seeds and only under N-rich conditions (Figs. 1(a) and 1(b)) [14]. In contrast, on Si substrates the NWs grew without any catalyst, but also only under N-rich conditions (Figs. 1(c)–1(f)) [17]. We therefore conclude that, as all the growth conditions were identical, whether or not a catalyst is necessary to induce the formation of NWs under the growth conditions employed depends only on the choice of substrate. The attempt to initiate the growth of catalyst-induced NWs on Si with Ni was unfruitful: Only large NiSi islands formed whereas the NWs grown on the areas free of these islands did not exhibit any catalyst at their tip. The diameters of the catalyst-induced NWs ranged from 15–60 nm with an average of 27 nm and their heights from 200–900 nm. The NW density was $2.5 \times 10^{10}$ NWs/cm$^2$. On Si, the diameters of the catalyst-free NWs varied from 15–100 nm with an average of 45 nm and their heights from 200–660 nm. The majority of these NWs were shorter than the NWs induced by the Ni seeds on sapphire. Such large dispersions in diameter and length have been attributed to the coalescence of short columns and enhanced growth of thinner ones through a diffusion-induced growth mechanism [18]. The catalyst-free NW density was slightly lower, namely $1.8 \times 10^{10}$ NWs/cm$^2$. These values are in agreement with Ref. [19]. In summary, the catalyst-induced NWs are on average longer and thinner than the catalyst-free analogs.

3.2 Crystal structure

Using both synthetic approaches, the GaN NWs obtained were single crystalline, having the wurtzite (WZ) structure and grew along the [0001] direction, as revealed by TEM [17, 20] and reflection high-energy electron diffraction (RHEED) (Figs. 2(a) and 2(b)). The spots in the RHEED patterns of the catalyst-induced NWs (Fig. 2(a)) and of the catalyst-free NWs (Fig. 2(b)) correspond to electron transmission through the WZ GaN structure [17]. The reflections for the self-induced NWs are arc-shaped (Fig. 2(b)), which indicates a slight spread in tilt relative to the substrate normal [21]. For the catalyst-induced approach, the presence of Ni particles at the NW tips shows that a VLS-like
mechanism promotes NW growth [20], while for the catalyst-free approach the NW tips are free of any particle [17]. The facet planes which constrict the NWs were identified by SEM (Figs. 1(g) and 1(h)) and X-ray diffraction. In both approaches, M-planes constitute the NW sidewalls. The same facet orientation has been reported before for catalyst-free GaN NWs [17] but it was not clear, a priori, that catalyst-induced NWs should grow in the same shape [22–24]. Although the crystal structure of the different types of NWs is the same, their polarity could still be different. Thus, convergent beam electron diffraction (CBED) experiments were carried out (Figs. 2(c) and 2(d)). Comparison of the experimental and the corresponding simulated patterns indicated that both the catalyst-free and catalyst-induced NWs are Ga-polar[1]. For the catalyst-free grown NWs, this result is in agreement with previous reports [21, 25], but for the catalyst-assisted NWs grown on sapphire it is somewhat surprising.

Figure 1  SEM images acquired at an angle of 90° (top), 45° (center), and 0° (bottom) to the surface normal. (a), (b), (g) Ni-induced NWs on C–plane sapphire. Catalyst-free-grown NWs ((c), (d), (h)) on Si(111) and ((e), (f)) on Si(001). The scale bars shown in the lower part of panel (a) and of panel (g) are 500 nm and 20 nm in length, respectively, and are valid for images ((a)–(f)) and ((g), (h)), respectively. The crystallographic orientations in (g) and (h) refer to the lattice of GaN and are based on complementary X-ray diffraction measurements

[1] For the CBED measurements, the catalyst-assisted and a catalyst-free NW sample grown at 780 °C and at 730 °C, respectively, were investigated. At the lower temperature of growth, SEM and RHEED of the catalyst-free NW sample showed no morphological difference from the high temperature sample. Thus it is legitimate to take this sample for the CBED comparison into consideration. Moreover, the results reported in Refs. [21, 26] were obtained on samples grown at 790 °C, and in the range of 700–800 °C, respectively.
While we are not aware of any literature on the polarity of catalyst-induced GaN NWs, planar layers of GaN grown on sapphire by MBE usually exhibit N-polarity [26]. However, the mechanisms leading to that polarity of planar layers and the possible influence of the nitridation of the sapphire are rather controversial [27, 28]. In any case, nucleation below the Ni catalyst instead of on the bare sapphire surface represents a significant change in the boundary conditions that may very well explain a difference in polarity between Ni-induced NWs and planar layers.

The defect structure of the GaN NWs was studied by TEM (Fig. 3). The catalyst-induced NWs contained many basal-plane stacking faults (SFs) randomly distributed along the NW axis. No other extended defects were found. These results are in agreement with those for similar NWs grown at lower temperature [14, 29], but the density of the SFs was higher in these cases, i.e. SF formation was reduced by increasing the growth temperature. In marked contrast, the catalyst-free NWs grown on Si were almost free of any SFs [17]. The SFs in the catalyst-induced NWs were found up to the tip, and as it will be later evidenced, both types of NWs were free of strain. Thus, the different types of substrates cannot be the reason for the discrepancy in crystal quality provided by the two approaches. In

Figure 2  ((a), (b)) RHEED and ((c), (d)) CBED patterns from GaN NWs grown ((a), (c)) catalyst-induced on Al2O3(0001) and ((b), (d)) catalyst-free on Si(111). The growth temperature of all these samples was 780 °C except for the sample investigated in (d) which was grown at 730 °C. In (a) and (b), the patterns were acquired along the (1210)GaN (top) and (1010)GaN (bottom) azimuths. For the CBED studies, the sample thicknesses were 4.5 nm and 5.3 nm in (c) and (d), respectively. Experimental patterns are on the left-hand side, with simulated ones on the right-hand side of each image. A Ga polarity was deduced in both cases
principle, the presence of many SFs in the catalyst-induced NWs could be attributed to their higher vertical growth rate. However, for the following reasons this explanation can also be excluded. First, the longest catalyst-free NWs whose growth rate was close to that of the catalyst-induced NWs were free of SFs. Second, the catalyst-induced NWs grew at a vertical rate of 0.2 nm/s. This is not an unusually high growth rate for planar GaN, but the catalyst-induced NWs contain many more SFs than the latter. Instead, there are several possible explanations for the SFs which are all related to the presence of the catalyst at the NW tip where growth takes place. First, the catalyst material may affect the crystal structure of the NW material. A RHEED study [15] revealed that the solid catalyst results in a cubic NiGa structure during NW growth. Thus, the binding configuration of the GaN nucleus at the NW-catalyst interface might adopt the zinc blende (ZB) configuration because it enables a more favorable bond orientation between the Ga-top layer and the cubic GaNi. This would be similar to the use of surfactants mediating the cubic nucleation of GaN films [30]. In this context it would be interesting to explore whether a hexagonal catalyst has the same effect. However, the search for suitable catalysts is beyond the scope of this manuscript. Second, Ni may also be incorporated to some extent and stabilize the ZB phase. Theoretical calculations indeed showed that the incorporation of impurities, like Si, Mg, In, and C, could reduce the ZB–WZ structural energy difference [31]. Furthermore, it has also been experimentally evidenced that Mg-doping of GaN NWs lead to the formation of stacking faults and double-twins whose density increased with the Mg concentration [32, 33]. Third, the catalyst introduces a triple phase line GaN–GaNi–vapor, and as described by Glas et al. for WZ GaAs NWs [34], preferential nucleation at this location could reverse whether ZB or WZ formation is favorable. Fourth, the formation of SFs could also originate from a lower surface mobility of adatoms at the NW tip, which could then be trapped at ZB sites [35–37]. This is consistent with the reduction of the SF density which was observed as the growth temperature was increased. However, the absence of SFs in the catalyst-free NWs directly identifies the catalyst particles as the origin of the reduced adatom kinetics.

3.3 Optical properties

For optoelectronic applications it is of crucial interest to know how the material quality affects the optical characteristics of the NWs and whether there is any difference in this respect between the two pathways. Low temperature (10 K) PL spectra were collected and their intensity was calibrated by comparison with that of a high quality GaN film taken as a reference sample (Fig. 4(a)). The spectra of all the samples revealed a clear emission line at 3.472 eV related to the donor-bound exciton transition (D0,X), characteristic of strain-free GaN [38]. The sharpest peak was obtained for the NWs grown on Si(111) and had a full-width at half-maximum of 3.1 meV. None of the samples exhibited the yellow band, which is an indication of very low densities of the related point defects for both the catalyst-assisted and catalyst-free pathways. However, there is a strong difference in the luminescence intensity of the NWs. The overall integrated...
intensity and the peak intensity of the \((D^0,X)\) line of the NWs obtained by the catalyst-free approach are, respectively, 6 and 25 times higher than the corresponding values for the catalyst-induced NWs.

Additional emission lines were detected at 3.43 eV for the catalyst-induced NWs, while the catalyst-free NWs exhibited emission features centered at 3.41–3.42 eV and 3.45 eV (Fig. 4(b)). For all these samples there appeared to be a multitude of transition lines in the range 3.41–3.43 eV. Emission in this energy range has been assigned in the bulk to structural defects, particularly SFs [39–41], and in catalyst-free NWs to structural defects at the NW–substrate interface [42]. Also in catalyst-free NWs, a blue-shift for increasing impurity concentration (Mg or Si) has been observed [43]. In Ni-induced GaN NWs a dominant emission at 3.437 eV has been tentatively attributed to neutral acceptor-bound excitons related to Ni contamination [44]. As discussed above, the main difference in the crystal quality between the two approaches is the occurrence of SFs. Thus, a shift from 3.41–3.42 eV for the catalyst-free NWs to 3.43 eV for the catalyst-assisted NWs might be the result of SFs and/or Ni contamination. The emission of the peak in the 3.41–3.43 eV region is much stronger compared to that of the \((D^0,X)\) transition for the catalyst-induced NWs than for the catalyst-free NWs. Also, we are not aware of any emission lines unambiguously due to Ni in GaN and SFs are known to be radiative defects. Therefore, it seems more reasonable to attribute the broad peak at 3.43 eV to SFs.

The emission at 3.45 eV is weaker in comparison to the \((D^0,X)\) transition in the case of growth on Si(001) than on Si(111) and not resolved in the case of growth on sapphire. This line is characteristic of catalyst-free GaN NWs grown by MBE [42]. It has been tentatively attributed to various structural features [42, 43, 45], and we cannot make any firm conclusions about the origin of this radiative transition.

The most striking of the above results is that the luminescence of the catalyst-free NWs was about 25 times stronger than that of the catalyst-induced NWs and this effect has been observed in a systematic manner for different samples. A quantitative comparison of PL intensities is difficult, but the difference between the catalyst-free and catalyst-induced NWs is so large that it must be a real effect. At this point we stress that the morphologies of the samples were very similar. The facet planes which constrict both types of NWs were identical, and the surface-to-volume ratio of both types of NWs differed by a factor of only 1.7, i.e., much less than the PL intensities. Both facts are essential to validate our comparison since surface recombination is especially critical for such nanostructures. First, the different recombination channels in these NWs do not originate from different defects characteristic of particular surfaces [24]. Second, the NW diameters are smaller than the exciton diffusion length (which may amount to 1 µm at low temperature) [46]. Therefore, the NW surface-to-volume ratio does

![Figure 4](image-url) (a) Low temperature (10 K) PL spectra of GaN NWs grown on a sapphire substrate with Ni seeds, on Si(111), and on Si(001). (b) Detail of the near band edge (semi-log scale)
not significantly influence the emission intensity. Possible differences in light extraction efficiencies do not suffice as an explanation, either. As discussed above, the structural difference, i.e., the occurrence of SFs in catalyst-induced NWs, may explain additional emission lines but not the reduced PL intensity. Besides, the position of the (D0,X) peak shows that in all cases the NWs are strain-free, which indicates that the effect of the different types of substrates is limited to the base of the NWs. Thus, the results strongly suggest the presence of an additional non-radiative recombination center in the catalyst-induced NWs, and the most plausible explanation is Ni contamination from the catalyst-seeds. This effect has not been reported before for GaN doped with Ni, which has in fact been rarely studied. However, Fe doping of GaN indeed leads to a strong decrease of the PL intensity [47] and of the luminescence decay times even at fairly low concentrations [48] by introducing very efficient non-radiative recombination channels. Ni and Fe are both 3d elements, and are known to possess similar properties as dopants in conventional III–V semiconductors. This strongly supports the conclusion that there is unintentional incorporation of Ni into the catalyst-induced NWs.

Direct measurements of the Ni concentration in catalyst-induced NWs have been hampered by tremendous experimental challenges [5–7]. In general, it is extremely difficult to detect impurities with a concentration significantly below 1% with a spatial resolution of nanometres, as is necessary in this case. Energy-dispersive X-ray analysis of Al0.2Ga0.8N catalyst-induced NWs grown via the same process and under the same conditions as the GaN NWs in this work showed Ni Kα line intensities only at the background level [49]. However, the sensitivity of PL experiments to impurities is much higher than any other technique. Therefore, while we do not have direct evidence for contamination due to the catalyst seeds, our results strongly suggest it.

4. Conclusions

We found two main differences between catalyst-induced and catalyst-free GaN NWs grown under identical conditions except for the choice of substrate. First, the catalyst-induced NWs contained a high density of basal-plane stacking faults whereas catalyst-free growth produced material largely free of stacking faults. Second, the peaks in the PL spectra of the catalyst-free NWs were much more intense and narrower. Both of these observations can be explained as effects of the catalyst Ni seeds. First, Ni contamination and/or the presence of an additional phase, i.e. the catalyst seed, may be the cause of the formation of SFs. Second, the direct comparison of growth routines in the same MBE chamber under identical conditions strongly suggests that Ni contamination is the cause of the significantly reduced PL intensity of the catalyst-induced NWs. The use of catalyst seeds may offer an additional way to control the growth of NWs, but both the structural and optical qualities of catalyst-free nanowires are superior.
