(Dated: September 25, 2012)

We report the experimental demonstration of two quantum networking protocols, namely quantum $1 \rightarrow 3$ telecloning and open-destination teleportation, implemented using a four-qubit register whose state is encoded in a high-quality two-photon hyperentangled Dicke state. The state resource is characterized using criteria based on multipartite entanglement witnesses. We explore the characteristic entanglement-sharing structure of a Dicke state by implementing high-fidelity projections of the four-qubit resource onto lower-dimensional states. Our work demonstrates for the first time the usefulness of Dicke states for quantum information processing.

PACS numbers: 42.50.Dv, 03.67.Bg, 42.50.Ex

Networking offers the benefits of connectivity and sharing, often allowing for tasks that individuals are unable to accomplish on their own. This is known for computing, where grids of processors outperform the computational power of single machines or allow the storage of much larger databases. It should thus be expected that similar advantages are transferred to the realm of quantum information. Quantum networking, where a given task is pursued by a lattice of local nodes sharing (possibly entangled) quantum channels, is emerging as a realistic scenario for the implementation of quantum protocols requiring medium/large registers. Key examples of such approach are given by quantum repeaters [1], non-local gates [2], scheme for light-mediated interactions of distant large registers [3] and one-way quantum computation [4].

In this scenario, photonics is playing an important role: the high reconfigurability of photonic setups and outstanding technical improvements have facilitated the birth of a new generation of experiments (performed both in bulk optics and, recently, in integrated photonic circuits [5]) that have demonstrated multi-photon quantum control towards high-fidelity computing with registers of a size inaccessible until only recently [6][11]. The design of complex interferometers and the exploitation of multiple degrees of freedom of a single photonic information carrier have enabled the production of interesting states, such as cluster/graph states, GHZ-like states and (phased) Dicke states [12][14], among others [15][16]. Dicke states have been successfully used to characterize multipartite entanglement close to fully symmetric states and its robustness to decoherence [14]. They are potentially useful resource for the implementation of protocols for distributed quantum communication such as quantum secret sharing [17], quantum teleporting (QTC) [18], and open destination teleportation (ODT) [19][20]. So far, such opportunities have only been examined theoretically and confirmed indirectly [12][13], leaving a full implementation of such protocols unaddressed.

In this Letter, we report the experimental demonstration of $1 \rightarrow 3$ QTC and ODT of logical states using a four-qubit symmetric Dicke state with two excitations realized using a high-quality hyperentangled (HE) photonic resource [14][21]. The entanglement-sharing structure of the state has been characterized quantitatively using a structural entanglement witness for symmetric Dicke states [22][23] and fidelity-based entanglement witnesses for the three- and two-qubit states achieved upon subjecting the Dicke register to proper single-qubit projections [13]. All such criteria have confirmed the theoretical expectations with a high degree of significance. As for the protocols themselves, the qubit state to teleclone/teleport is encoded in an extra degree of freedom of one of the physical information carriers entering such multipartite resource. This has been made possible by the use of a displaced Sagnac loop [24] [cf. Fig. 1], which introduced unprecedented flexibility in the setting, allowing for the realization of high-quality entangling two-qubit gates on heterogeneous degrees of freedom of a photon within the Sagnac loop itself. The high fidelities achieved between the experiments and theory (as large as 96%, on average, for ODT) demonstrate the usefulness of Dicke states as resources for distributed quantum communication beyond the limitations of a “proof of principle”. Our scheme is well suited for implementing $1 \rightarrow N>3$ QTC of logical states or ODT with more than three receivers via the realization of larger HE resources, which is a realistic possibility.

Resource production and state characterization. - The building block of our experiment is the source of two-photon four-qubit polarization-path HE states developed in [21][25] and used recently to test multi-particle entanglement, decoherence and general quantum correlations [14][26][27]. Such apparatus has been modified as described in the Supplementary Information [29] to produce the HE state $|\xi\rangle_{abcd}=|HH\rangle_{ab}|rl\rangle_{cd}+|VV\rangle_{ab}|rl\rangle_{cd}/\sqrt{6}$. Here, we have used the encoding $(|H\rangle,|V\rangle)=\{0,1\}$, with $H/V$ the horizontal/vertical polarization states of a single photon, and $(|r\rangle,|l\rangle)=\{0,1\}$, where $r$ and $l$ are the path followed by the photons emerging from the HE stage [29]. Qubits $a,c (b,d)$ are encoded in the polarization and momentum of photon A (B). State $|\xi\rangle$ is turned into a four-qubit two-excitation Dicke state $|D_2^{(2)}\rangle=\sqrt{2} \sum_i \big{|}\Pi_i\big{)}$ with $|\Pi_i\rangle$ the elements of the vector of states constructed by
taking all the permutation of 0’s and 1’s in |0011⟩) by means of unitaries arranged as specified in Ref. [14] [cf. Fig. 1(a)]. In the basis of the physical information carriers, the state reads |D_k⟩=(|HHHT⟩+)([Vrrr] ([VVrr]([HV] + [HV]))(|rr⟩ + |rr⟩)/√6). The fidelity of the protocols depends on the quality of this state, as will be clarified soon. We have thus tested the closeness of the experimental state to |D_k⟩ and characterized its entanglement-sharing structure.

First, we have ascertained the genuine multipartite entangled nature of the state at hand by using tools designed to assess the properties of symmetric Dicke states [22, 23, 28].

We have considered the multipartite entanglement witness

$$\mathcal{W}_m = \frac{[24 \mathbb{I} + 24 \hat{S}_x + 24 \hat{S}_y + 24 \hat{S}_z (31 \mathbb{I} - 7 \hat{P}_z)]}{12},$$

which is specific of |D_4⟩ [23] and requires only three measurement settings. Here, $\hat{S}_{x,y,z} = \sum_{i=0}^{3} \sigma_{i}^{x,y,z}/2$ collective spin operators, $\sigma^{j}$ (j=x, y, z) the j-Pauli matrix and $Q = \{a, b, c, d\}$. The expectation value of $\mathcal{W}_m$ is positive on any bi-separable four-qubit state, thus negativity implies multipartite entanglement. Its experimental implementation allows to provide a lower bound to the state fidelity with the ideal Dicke state as $F_{|D_4⟩} \geq (2 - \langle \mathcal{W}_m \rangle)/3$.

When calculated over the resource that we have created in the lab, we achieve $\mathcal{W}_m = -0.341 \pm 0.015$, which leads to $F_{|D_4⟩} \geq (78 \pm 0.5\%)$. The genuine multipartite entangled nature of our state is corroborated by another significant test: we consider the witness testing bi-separability on multipartite symmetric, permutation invariant states like our $|D_4⟩$ [13, 28]

$$\mathcal{W}_{\gamma}(\gamma) = b_4(\gamma) \mathbb{I} - (\hat{F}_1^z + \hat{F}_2^z + \gamma \hat{F}_3^z) \quad (\gamma \in \mathbb{R}).$$

Here $b_4(\gamma)$ is the maximum expectation value of the collective spin operator $\hat{F}_1^z + \hat{F}_2^z + \gamma \hat{F}_3^z$ over the class of bi-separable states of four qubits and can be calculated for any value of the parameter $\gamma$. Finding $\langle \mathcal{W}_{\gamma}(\gamma) \rangle < 0$ for some $\gamma$ implies genuine multipartite entanglement. The direct evaluation shows that already for $\gamma = -0.12$ the witness is negative by more than one standard deviation and by more than fifteen for $\gamma = -2.5$ (cf. SI [29]).

These results, although indicative of high quality of the resource produced, are not exhaustive and further evidence is needed. In order to provide an informed and experimentally not-demanding analysis on the state being generated, we have decided to resort to indirect yet highly significant evidence on its properties. In particular, we have exploited the interesting entanglement structure that arises from |D_4⟩ upon subjecting part of the qubit register to specific single-qubit projections. In fact, by projecting one of the qubits onto the logical (0) and (1) states, we maintain or lower the number of excitations in the resulting state without leaving the Dicke space, respectively.

Indeed, we achieve $|D_4⟩ = (\langle 011 \rangle + \langle 010 \rangle + \langle 100 \rangle + \langle 001 \rangle)/\sqrt{3}$ when projecting onto (0), while $|D_4⟩ = (\langle 000 \rangle + \langle 010 \rangle + \langle 001 \rangle)/\sqrt{3}$ is obtained when the projected qubit is found in (1). Needless to say, these are genuinely tripartite entangled states, as it can be ascertained by using the entanglement witness formalism. For this task we have used the fidelity-based witness [30]

$$\mathcal{W}_{D_4}(\gamma) = (2/3) - |\mathcal{D}_4(2)\rangle \langle \mathcal{D}_4(2)| \quad (k = 1, 2),$$

which is positive for any separable and bieeparable three-qubit state, is $-1/3$ when evaluated over $|D_4⟩$ and whose optimal decomposition (cf. SI [29]) requires five local measurement settings [34, 31].

We have implemented the witness for states obtained projecting qubit (i.e. momentum of photon B), achieving $\langle \mathcal{W}_{D_4}(\gamma) \rangle = -0.21 \pm 0.01$ and $\langle \mathcal{W}_{D_4}(\gamma) \rangle = -0.24 \pm 0.01$ (the apex indicates their experimental nature) corresponding to lower bounds for the fidelity with the desired state of 0.876 ± 0.003 and 0.908 ± 0.003, respectively.

Finally, by projecting two qubits onto elements of the computational basis, one can obtain elements of the Bell basis. Indeed, regardless of the projected pair of qubits, $\langle i\bar{j}\mathcal{D}_4(2)\rangle = \langle \psi^+ \rangle$ with $\langle \psi^+ \rangle = (\langle 01 \rangle \pm \langle 10 \rangle) / \sqrt{2}$, $\langle \phi^+ \rangle = (\langle 00 \rangle \pm \langle 11 \rangle) / \sqrt{2}$ the Bell basis and $\theta = 0, 1$. We have verified the quality of the reduced experimental states achieved by projecting the Dicke state onto $|10⟩_{cd}$ and $|01⟩_{cd}$ using two-qubit quantum state tomography (QST) [32] on the remaining two qubits. By finding fidelities >91% regardless of the projections operated, we can claim to have a very good Dicke resource, which puts us in the position to experimentally implement the quantum protocols.

1-3 QTC and ODT: Telecomoning [18] is a communication primitive that merges teleportation and cloning to deliver approximate copies of a quantum state to remote nodes of a network. Differently, ODT [19] enables the teleportation of a state to an arbitrary location of the network. Both require shared multipartite entanglement. A deterministic ver-
sion of ODT makes use of GHZ entanglement [20], while the optimal resources for QTC are symmetric states having the form of superpositions of Dicke states with $k$ excitations [18, 16, 11, 8, 33]. Continuous-variable QTC was demonstrated in [35]. Although a symmetric Dicke state is known to be useful for such protocols (ODT being reformulated probabilistically) [12], no experimental demonstration has yet been reported: in Ref. [12], only an estimate of the e

We start discussing the 1→3 QTC scheme based on $|D_{4}^{(2)}⟩$, which is a variation of the protocol given in Ref. [18]. We consider the qubit state to clone $|α⟩_{X} = α|0⟩_{X} + β|1⟩_{X} (|α|^2 + |β|^2 = 1)$, held by a client $X$. The agents of a server composed of qubits $a, b, c, d$ and sharing the Dicke resource agree on the identification of a port qubit $p$. The state of pair $(X, p)$ undergoes a Bell measurement (BM) performed by implementing a controlled-NOT gate $CX_{xp}$ followed by a projection of $X$ (by) on the eigenstates of $δ^z$ ($δ^x$). They publicly announce the results of their measurement, which leaves us with

$$\bigotimes_{j\in S_{tc}} P_{j}(α|D_{4}^{(2)}⟩+β|D_{4}^{(2)}⟩),$$

where $S_{tc}=(a,b,c,d)/p$ is the set of server’s qubits minus $p$, and $|D_{4}^{(2)}⟩$ is a three-qubit Dicke state with $k=1, 2$ excitations and the gates $P_{j}$ (identical for all the qubits in $S_{tc}$) are determined by the outcome of the BM, as illustrated in Fig.1(d). The protocol is now completed and the client’s qubit is cloned into the state of the elements of $S_{tc}$. To see this, we track out two of the elements of such set and evaluate the state fidelity between the density matrix $ρ_j$ of the remaining qubit $r$ and the client’s state, which reads $F(θ)=[9-\cos(2θ)]/12$, where $α=\cos(θ/2)$. Clearly, the fidelity depends on the state to clone, achieving a maximum (minimum) of $5/6 (2/3)$ at $θ = π/2 (θ = 0, π)$. This exceeds the value $7/9$ achieved by a universal symmetric 1→3 cloning due to the state-dependent nature of our protocol.

We now introduce the ODT protocol. As for QTC, this is formulated as a game with a client and a server. The client holds qubit $X$, into which the state $|α⟩_{X}$ to teleport is encoded. The elements of the server share the $|D_{4}^{(2)}⟩$ resource. The client decides which party $r$ of the server should receive the qubit to teleport ($r$ and $p$ can be any of $a, b, c, d$, and $r$ is chosen at the last step of the scheme). Unlike QTC, the client performs a $CX_{xp}$. At this stage the information on the qubit to teleport is spread across the server, and the client declares who will receive it. Depending on his choice, the members in $S_{odt}=[a,b,c,d]/[r,p]$ project their qubits onto $|01⟩_{S_{odt}}$, getting $[α(001)+(010)]_{xp} + β(111)+(100)]_{xp} ⊗ |01⟩_{S_{odt}}$. The scheme is completed by a projection onto $|1⟩_{xp}$ with $+|(00)⟩_P$. No change is made to the path DOF. The remaining qubits $(a,c,d)$ embody copies of the qubit $X$. They are removed by performing QST over the reduced states obtained by tracing over any two qubits. Pauli operators in the path DOF have been measured using the second passage of both photons through $BS_2$. The probability of being in the former (latter) state relates to the transmittivity (reflectivity) of $BS_2$. This probability is varied using intensity attenuators intercepting the output modes of $BS_2$. At this stage, the state of the register is $|D_{4}^{(2)}⟩_{abcd} ⊗ (|α⟩_X + e^{iφ_x} \sqrt{1-|α|^2})_{X}$, where $φ_x$ is the polarization of photon $B$ as the port $p$ and taking a HWP rotated at $45^\circ$ with respect to the optical axes, placed only on the counterclockwise circulating modes of the Sagnac loop [37]. The second passage of the lower photon in $BS_2$ allows to project qubit $X$ on the eigenstates of $δ^z_x$. To complete the Bell measurement on qubits $(X, p)$ we have placed a HWP and a PBS before the detector in order to project qubit $p$ on the eigenstates of $δ^z_p$. The remaining qubits $(a,c,d)$ embody copies of the qubit $X$. Their quality has been tested by performing QST over the reduced states obtained by tracing over any two qubits. Pauli operators in the path DOF have been measured using the second passage of both photons through $BS_1$. The glass plates $φ_{A,B}$ allowed projections onto $\frac{1}{√2}(|r⟩+e^{iφ_{A,B}}|ℓ⟩)_{cad}$. To perform QST on the polarization DOF we used an analyzer composed of HWP, QWP and PBS before the photo-detector. To trace over polarization, we removed the analyzer. To trace over the path, a delay was placed on either $|r⟩$ or $|ℓ⟩$ coming back to $BS_1$, thus making

![FIG. 2: (Color online) a) Experimental QTC: for an input state $|1⟩_X$, the ideal output state is $(2|0⟩_X⟨0|+|1⟩_X⟨1|)/3, \forall j=a,c,d$ [left column of the panel]. The state of qubit $j$ after the experimental QTC, has very large overlap with the theoretical state. The right column of the panel shows the experimental single-qubit density matrices. b) Theoretical QTC fidelity and experimental density matrices of the clone (qubit $a$) for various input states. We show the fidelities between the experimental input states and clones (associated uncertainties determined by considering Poissonian fluctuations of the coincidence counts). The dashed line shows the theoretical fidelity for pure input states of the client’s qubit. The dashed area encloses the values of the fidelity achieved for a mixed input state of $X$ and the use of an imperfect Dicke resource compatible with the states generated in our experiment (cf. SI [32]).](image-url)
them distinguishable and spoiling their interference.

In Fig. 2(a) we show the experimental results obtained for the input states $|1⟩_X$, when $p=b$. QST on qubit $j=a, c, d$ shows an almost ideal fidelity with the theoretical state, uniformly with respect to label $j$, thus proving the symmetry of QTC. Our setup allows us to teleport arbitrary input states. To illustrate the working principles and efficiency of the telecloning machine, we have considered the logical states $|0⟩_X$ and $|+⟩_X$ and $|1⟩_X$ (i.e. we took $\theta=0, \pi/2$ and $\pi$) and measured the corresponding copies in qubit $a$ (i.e. the polarization of photon $A$). States $|0⟩_X$ and $|1⟩_X$ were generated by selecting the modes in the displaced Sagnac. In the first (second) case we considered only modes $|\phi⟩$ (i.e. $|\phi⟩$), while $|+⟩_X$ was generated using both modes and adjusting the relative phase with the glass plate $\phi_X$ (by varying this phase, we can explore the whole phase-covariant case). Although the experimental results are very close to the expectations for $F(\theta)$ [cf. Fig. 2(b)], some discrepancies are found for $\theta = \pi/2$. In particular, the theory seems to underestimate (overestimate) the experimental fidelity of teleporting close to $\theta = \pi/2 (\theta = 0, \pi)$. These effects are due to the mixedness of the $X$ state entering the Sagnac loop as well as the suboptimal fidelity between the experimental resource and $|D^{21}_X⟩$. In fact, the experimental input state corresponding to $\theta \approx \pi/2$ has fidelity $0.91 \pm 0.02$ with the desired $|+⟩_X$ due to depleted off-diagonal elements in its density matrix (cf. SI 23). We have thus modelled the telecloning of dephased client states based on the use of a mixed Dicke channel of sub-unit fidelity with $|D^{21}_X⟩$. The details are presented in Ref. 23. Here we mention that, by including the uncertainty associated with the estimated $F_{D^{21}_X}$, we have determined a $\theta$-dependent region of telecloning fidelities into which the fidelity between the experimental state of the clones and the input client state falls. As shown in Fig. 2(b), this provides a better agreement between theory and data.

Experimental implementations of ODT.- In ODT the client holds qubit $X$, which is added to the computational register using the Sagnac loop. The client’s qubit has been teleported to the server’s elements $a$ and $b$ (i.e. the polarization of photons $A$ and $B$). The necessary CNOT gate has been implemented, as above, by taking $X$ as the control and $p=b$ as the target qubit. The server’s elements $c, d$ have been projected onto $|0⟩_{cd}$ and $|1⟩_{cd}$. Depending on the chosen receiver (either $a$ or $b$), the scheme is implemented by projecting onto $|+⟩_{X(a,b)}$ and performing QST of the teleported qubit $b(a)$. While the projection onto $|+⟩_X$ has been realized using the second passage of the lower photon through BS$_2$, a projection onto $|1⟩_{ab}$ is achieved projecting the physical qubit onto $|V⟩_{ab}$. In Table I we report the experimental results obtained for several measurement configurations and teleportation channels. In SI 29 we provide the reconstructed density matrices of qubits $X, a, b$ for each configuration used.

Conclusions and outlook.- We have implemented QTC and ODT of logical states using a four-qubit symmetric Dicke state. We have realized a novel setup based on the well-tested HE polarization-path states and complemented by a displaced Sagnac loop. This allowed the encoding of non-trivial input states in the computational register, and the performance of high-quality quantum gates and protocols. Our results go beyond state-of-the-art in the manipulation of experimental Dicke states and the realization of quantum networking.

Acknowledgments.—We thank Valentina Rosati for the contribution given to the early stages of this work. This work was supported by EU-Project CHISTERA-QUASAR, PRIN 2009 and FIRB-Futuro in ricerca HYTEQ, and the UK EPSRC (EP/G004579/1).

SUPPLEMENTARY INFORMATION ON: EXPERIMENTAL QUANTUM NETWORKING PROTOCOLS VIA FOUR-QUBIT HYPERENTANGLED DICKE STATES

Here we describe the source of hyperentanglement that has been used as the building block of our experiment. As remarked in the text of the Letter, we use the encodings \(|H⟩, |V⟩⟩\equiv |0⟩, |1⟩\rangle\), with \(H/V\) the horizontal/vertical polarization states of a single photon, and \(|r⟩, |ℓ⟩⟩\equiv |0⟩, |1⟩\rangle\), where \(r\) and \(ℓ\) are the path followed by the photons emerging from the HE stage introduced and exploited in [14, 21, 25, 27].

We modify such setup so to prepare the HE resource \(|\xi⟩_{abcd}\equiv |HH⟩_{ab}(|rℓ⟩−|ℓr⟩)_{cd}+2|VV⟩_{ab}|rℓ⟩_{cd}/\sqrt{6}\rangle\rangle\) introduced in the main Letter. A sketch of the apparatus is shown in Fig. 3. A Type-I nonlinear β-barium borate crystal, pumped by a vertically polarized laser field (wavelength \(λ_p\)), generates a polarization-entangled state given by the superposition of the spontaneous parametric down conversion (SPDC) signals at degenerate wavelength produced by a double-pass scheme. The mask selects four spatial modes \(|r⟩, |ℓ⟩⟩\), \(a, b\) (two for each photon), parallelized by lens L. QWP\(_{1,2}\) are quarter-wave plates. The first pass produces \(2|VV⟩|rℓ⟩\). The spatial modes are intercepted by two beam stoppers. QWP\(_1\) changes the polarization into \(VV\) after reflection by mirror M. The latter also reflects the pump, which produces the second-pass SPDC contribution \(|HH⟩(|rℓ⟩−|ℓr⟩)\rangle\rangle\). The weight of this term in the final state \(|ξ⟩\) is determined by QWP\(_2\) [14].

ON ENTANGLEMENT WITNESSES FOR GENUINE MULTIPARTITE ENTANGLEMENT

Collective-spin operators are useful tools for the investigation of genuine multipartite entanglement, particularly for symmetric, permutation invariant states. One can construct the witness operator [38]

\[\mathcal{W}_γ = b_n \mathbb{1} - (\hat{J}_x^2 + \hat{J}_y^2),\]  

where \(b_n\) is the maximum expectation value of \(\hat{J}_x^2 + \hat{J}_y^2\) over the class of bi-separable states of \(n\) qubits. Finding \(\langle \mathcal{W}_γ \rangle < 0\) for a given state implies genuine multipartite entanglement. It can be the case that Eq. (3) fails to reveal the multipartite nature of a state endowed with a lower degree of symmetry. More flexibility can nevertheless be introduced by means of a suitable generalization such as

\[\mathcal{W}_c(γ) = b_n (γ) \mathbb{1} - (\hat{J}_x^2 + \hat{J}_y^2 + γ \hat{J}_z^2) \quad (γ \in \mathbb{R}).\]  

Negativity of \(\langle \mathcal{W}_c(γ) \rangle\) over a given state guarantees multipartite entanglement. The witness requires only three measurement settings and is thus experimentally very convenient. The bi-separability bound \(b_n(γ)\) is now a function of parameter \(γ\) and can be calculated numerically using the procedure described in Ref. [28]. In general, \(b_n(γ) < b_n(0)\) for \(γ < 0\). Consequently, we restrict ourselves to the case of negative \(γ\).

In Table II we provide the experimental values of \(\langle \hat{J}_z^2⟩\) through which we have evaluated Eq. (4), which is plotted against \(γ\) in Fig. 4. While \(\langle \mathcal{W}_c(γ) \rangle\) soon becomes negative as \(γ < −0.1\) is taken, the uncertainty associated with such expectation value, calculated by propagating errors in quadrature as

\[δ⟨\mathcal{W}_c(γ)⟩ = \sqrt{\sum_{j=x,y} (δ⟨\hat{J}_j^2⟩)^2 + γ^2 (δ⟨\hat{J}_z^2⟩)^2},\]

 grows only very slowly with \(γ\), therefore signaling an increasingly significant violation of bi-separability.

OPTIMAL DECOMPOSITION OF THE ENTANGLEMENT WITNESS FOR \(|D_1⟩\)

As discussed in the main body of the Letter, we have used a fidelity-based entanglement witness to characterize the genuine tripartite entanglement content of the state achieved

| Expectation value (with uncertainty) | Value |
|-----------------------------------|-------|
| \langle \hat{J}_1^2 \rangle ± δ(\hat{J}_1^2) | 2.568±0.015 |
| \langle \hat{J}_2^2 \rangle ± δ(\hat{J}_2^2) | 2.617±0.011 |
| \langle \hat{J}_3^2 \rangle ± δ(\hat{J}_3^2) | 0.039±0.028 |

TABLE II: Experimentally measured expectation values of collective spin operators for the symmetric four-qubit Dicke state prepared in our experiment. The uncertainties are determined by associating Poissonian fluctuations to the coincidence counts.
upon projecting one of the qubits onto a state of the logical computational basis. Without affecting the generality of our discussion, here we concentrate on the case of a qubit-projection on qubit \(d\) giving outcome \(|\alpha\rangle_d\), thus leaving us with state \(|D_{i}^{(3)}\rangle_{abc}\). The fidelity-based witness that we have implemented is given in the main Letter and is decomposed in five measurement settings as \[(6)\]

\[
\mathcal{W}_{D_{i}^{(3)}} = \frac{1}{24}\left[17\mathbb{1} + 7\hat{\sigma}_a^x\hat{\sigma}_b^x\hat{\sigma}_c^x + 3\mathcal{F}\hat{\sigma}_a^x\hat{\sigma}_b^x\hat{\sigma}_c^x + 5\mathcal{F}\hat{\sigma}_a^x\hat{\sigma}_b^y\hat{\sigma}_c^y + \sum_{x=y}^{z}
\sum_{y=x}^{z}(\hat{\sigma}_a^x + \hat{\sigma}_b^x + \hat{\sigma}_c^x)(\mathbb{1} + \hat{\sigma}_a^y + \hat{\sigma}_b^y + \hat{\sigma}_c^y)(\mathbb{1} + \hat{\sigma}_a^z + \hat{\sigma}_b^z + \hat{\sigma}_c^z)\right]
\]

where \(\hat{\mathcal{F}}\) performs the permutation of the indices of its argument. The decomposition is optimal in the sense that \(\mathcal{W}_{D_{i}^{(3)}}\) cannot be decomposed with lesser measurement settings. Experimentally, we have used the following rearrangement of the previous expression

\[
\mathcal{W}_{D_{i}^{(3)}} = \frac{1}{24}\left[13\mathbb{1}_{abc} + 3\hat{\sigma}_a^x\hat{\sigma}_b^x\hat{\sigma}_c^x - \mathcal{F}\hat{\sigma}_a^x\hat{\sigma}_b^y\hat{\sigma}_c^y + \mathcal{F}\hat{\sigma}_a^x\hat{\sigma}_b^y\hat{\sigma}_c^z - 2\mathcal{F}\hat{\sigma}_a^x\hat{\sigma}_b^z\hat{\sigma}_c^y - 2\mathcal{F}\hat{\sigma}_a^x\hat{\sigma}_b^z\hat{\sigma}_c^z - 2\mathcal{F}\hat{\sigma}_a^y\hat{\sigma}_b^y\hat{\sigma}_c^z - 2\mathcal{F}\hat{\sigma}_a^y\hat{\sigma}_b^z\hat{\sigma}_c^z + \mathcal{F}\hat{\sigma}_a^z\hat{\sigma}_b^z\hat{\sigma}_c^z\right],
\]

which was easier to implement with our setup.

**FIDELITY OF QUANTUM TELECLONING FOR MIXED STATES OF THE CLIENT**

Here we provide a model for the solid (red) line of Fig. 2 (b) accounting for the fidelity of quantum telecloning of a client’s mixed state. The evaluation of the theoretical fidelity of telecloning given in the main Letter does not take into account the mixed nature of the client’s state, as well as the non-ideality of the experimental Dicke channel used for the scheme. As argued in the main Letter, these are the main sources of discrepancy between the experimental results and the theoretical predictions. Here we provide a simple model that includes these imperfections and allows for a more faithful comparison between theoretical predictions and experimental data.

Our starting point is the observation that mixed input states of the client can correspond to telecloning fidelities larger than the theoretical values predicted by \(\mathcal{F}(\theta) = [9 - \cos(2\theta)]/12\). This can be straightforwardly seen by running the quantum telecloning protocol with a decohered state resulting from the application of a dephasing channel to a pure client’s state of the form \(|\alpha\rangle_X + \beta|1\rangle_X\) with \(\alpha = \cos(\theta/2)\) as in the main Letter. This is illustrated in Fig. 2 of the main Letter. Quite intuitively, as the input client’s state loses its coherences, the fidelity of telecloning improves. The second observation we make is that the entangled channel used in our experiment, although being of very good quality, has a non-unit overlap with an ideal Dicke resource. Taking into account the major sources of experimental imperfections, along the lines of the investigation in [14], a reasonable description of the four-qubit resource produced in our experiment is the Werner-like state

\[
\rho_D = p|D_{ii}^{(2)}\rangle\langle D_{ii}^{(2)}| + (1 - p)\mathbb{1}/16
\]

with \(0 \leq p \leq 1\). The entangled Dicke component in such a state is evaluated considering that our experimental estimate for the lower bound on the state fidelity is \(F_{\rho_D^{(2)}} = (0.78 \pm 0.5)\). Moreover, we have checked that slight experimental imperfections in the determination of the populations of the input client’s states (within the range observed experimentally) do not affect the overall picture significantly. We have thus incorporated the effects of a coherence-depleted input states of qubit X into the protocol for \(1 \rightarrow 3\) quantum telecloning performed using a mixed Dicke resource as in Eq. \((8)\). The dephasing parameter used in the model for mixed client’s state has been adjusted so that, at \(\theta = \pi/2\), we get the real part of the experimentally reconstructed off-diagonal elements of the density matrix of qubit X (fixed relative phases between \(|0\rangle_X\) and \(|1\rangle_X\) do not modify our conclusions). The resulting state fidelity, shown in Fig. 2 (b) of the main letter, shows a very good agreement with the experimental data.
FIG. 5: We report the reconstructed density matrices of the telecloned states measured on qubit \( a \), for three different input client’s states (qubit \( X \)).

**SINGLE-QUBIT QUANTUM STATE TOMOGRAPHY OF RECEIVERS’ STATES IN EXPERIMENTAL QTC AND ODT**

In Fig. 5 (Fig. 6) we give the single-qubit density matrix obtained through quantum state tomography of the receiver’s state in the QTC (ODT) protocol. The telecloned states reported in Fig. 5 have been shown in Fig. 2 b) of the main letter. We have considered three different input client’s states. For each of them, we have measured the telecloned state on the qubit \( a \).

The values of state fidelity included in the Figure 6 are those reported in Table I of the main Letter. We have considered four different input client’s states. For each of them, we have projected the server’s elements onto either \( |01\rangle_{S,odt} \) or \( |10\rangle_{S,odt} \) and taken qubit \( a \) or \( b \) as he receiver. The corresponding quantum state fidelities are evidently quite uniform and consistently above 90% (mean fidelity 0.96 ± 0.01), thus demonstrating high-quality and receiver-oblivious ODT.
