Self-Powered Soil Moisture Monitoring Sensor Using a Picoampere Quiescent Current Wake-up Circuit

Masoud Kargaran, Mehdi Habibi and Sebastian Magierowski, Member, IEEE

Abstract—Low power wireless standalone sensors which can operate without any wiring have received significant attention in sensor network applications. These devices harvest environmental energy resources to supply their power and transfer their collected data using wireless RF links. In many instances the power supplied from the environment is far less than the power required by the sensor device. In this case the main solution is to accumulate energy on a storage element and when enough energy is stored, the sensor node is instantaneously activated using an under voltage lockout, UVLO, circuit. During this short time burst, the sensor performs the required acquisition, transmits the results and enters a sleep mode until again enough energy is collected. The quiescent current of the UVLO is the main factor that determines the minimum power level at which the sensor node is still operational. Most wake-up circuits used in conventional devices suffer from a quiescent current of a few hundred nanoamperes. In this work, using a zero bias current MOSFET based approach, a new wake-up circuitry is presented which lowers the quiescent current down to the picoampere range. As a practical application, the effectiveness of the proposed circuit is shown in a soil moisture monitoring sensor setup.

Index Terms—Energy harvesting, Low power electronics, MOSFET circuits, Soil moisture monitoring, Sensors

I. INTRODUCTION

W
ith the advances achieved in telecommunications and wireless systems, wireless sensors nodes have found wide application in different fields of industry [1]–[3], agriculture [4] and environmental protection. They are extensively used for monitoring of a wide area using multiple numbers of smaller local sensors. The problem with this scenario is that the battery replacement of many units is difficult. Many successful monitoring sensor node setups supply the power of the units using environmental energies [5], [6]. Solar power is one of the most common solutions; however at indoor setups the supplied power is considerably low [7]. Other alternatives have also been considered for harnessing of surrounding energies such as the use of environmental vibrations [8], [9], electromagnetic waves, environment heat and magnetic fields [10], [11]; however these sources also deliver limited energy to the operational device and generally smaller energy harvesters which are integrated with the electronic circuit board harness lower power.

A lot of research has been devoted on the design of high efficiency voltage rectifiers, charge pumps, switching DC-DC converters (buck/boost) [12], [13] and low drop out regulators in energy harnessing sensor nodes to minimize the power dissipation of the power delivery blocks. Appropriate zero bias current circuits can also help increase the efficiency of the available power [14].

When the harnessed power is much lower than that required by the electronic circuits an effective approach known as sleep/wake-up is used. In this method all units, even the switching converter and linear regulators, are put to sleep and energy is accumulated on a storage element such as a super capacitor with low leakage current. When enough energy is accumulated, it is transferred momentarily to the electronic circuits [15]–[17]. The circuit which monitors this event is known as the wake-up block or under voltage lockout, UVLO, detector. Technically the UVLO is a Schmitt trigger [18] and commonly used architectures for such a device include opamp-based and CMOS inverter-based topologies.

UVLO circuits are commercially available in voltage supervisors and charger devices such as LTC3588 and its similar families [19], [20]. However, most circuits presented so far have a quiescent current of a few hundred nano amperes. Reducing this value will be advantageous since it means that the sensor node can be operated with lower levels of available transducer power.

In this work a new topology is presented which reduces the quiescent current of the UVLO circuit and thus lowers the harvester power dissipation. The concept presented here uses non-overlapping activation of pull-up and pull-down switches in the output stage of the UVLO circuit. Using positive feedback, the amount of time required for the output signal state change is decreased. The required reference-level voltages are also generated using a low-power subtractor. The performance of the proposed approach is investigated using both simulation and experimental setups. Also, a working proof of the concept is presented to show the effectiveness of the approach in a wireless and self-powered soil moisture monitoring sensor.

The rest of the paper is organized as follows: In section II energy harnessing sensor nodes and the function of UVLO circuits in these devices is explained. The proposed circuit and its analyses are presented in section III. Simulation and experimental results are given in section IV. Finally concluding remarks are presented in the last section.
A typical configuration of an electronic energy harvesting system used in sensor network devices is shown in Fig. 1. In sensor network applications, the power requirements are relatively low and thus simple environmental energy harvesters such as small solar panels, RF antennas, piezoelectric elements, electro-dynamometric generators and thermopile transducers are appropriate choices. These devices, shown as the power source block in Fig. 1, produce limited power output and suitable designs must be considered to minimize any source of power dissipation for efficient operation.

The system shown in Fig. 1 includes the frontend energy harvesting transducer (power source), the rectifier which can be used to convert AC voltage sources to a DC potential. A voltage multiplier or charge pump can also be used instead of this block if higher $V_{\text{power}}$ potentials are required. This voltage then enters the DC-DC converter to convert the input voltage required by the electronic circuitry of the final stage. Switching DC-DC converters help perform this conversion with lower power dissipation compared with linear regulators. A maximum power point tracking (MPPT) controller can also be used to help extract the maximum available power from the rectifier. The low drop out regulator in the final stage helps to better regulate the achieved voltage and to remove any unwanted voltage ripples from the switching converter. The achieved $V_{DC}$ voltage can now be used for all other electronics including the sensor, processor and wireless transmitter.

Fig. 2(a) shows the configuration of the Schmitt trigger (UVLO) block in the energy harnessing system. The load shown in the figure represents all electronic blocks after the rectifier, including the DC-DC converter or MPPT circuits. The harvesting frontend is also modeled with the current source, $I_s$, charging a storage capacitor, $C_s$.

II. CONVENTIONAL UVLO

The current–voltage characteristic of the typical electronic power consuming block is shown in Fig. 3(a). The operational region of these devices is at supply voltages above the nominal level, $V_{\text{nom}}$. With no UVLO circuit, if lower powers are available, the electronic blocks will still draw current and dissipate power; however the provided power cannot place the electronic circuitry at a suitable operation point. As shown in Fig. 3(b), while the consumed average power remains equal to $P_i$, with an UVLO the operation point can move between points B and C which is suitable for the operation of the load electronic circuitry.

Opamp-based and inverter-based Schmitt triggers have conventionally been used for ULVO realization. In the opamp-based approach, 2 opamps are used to compare the accumulated input voltage with 2 different reference levels. If the voltage is higher than the upper threshold limit, $V_T+$, the Schmitt trigger latches into the wake-up state, and if lower than the lower threshold limit, $V_T-$, it latches into the sleep state. The static current of the two opamps is the main source of quiescent current in this case. Although CMOS inverter-based Schmitt triggers avoid the static current of the opamp-based approach, however whenever the input is crossing the upper/lower threshold limit, a short circuit current will be drawn from the supply resulting in a specific average quiescent current throughout the periodic cycle.

III. PROPOSED METHOD

Similar to a CMOS inverter gate, the core of the proposed Schmitt trigger is composed of a nMOS (Mno) and a pMOS (Mpo) device, however for all input voltages these two devices are never activated simultaneously even in transient states to avoid any static currents. With the proposed configuration, three states can be considered for the nMOS-pMOS pair. When Mno is on, the output is low and when the Mpo switch is on, the output is high. Finally, if both Mno and Mpo devices are off, the output retains its previous value. As shown in Fig. 2(b), the idea is to connect the input voltage, $V_i$, to Mpo and $V_i - V_{shift}$ to Mno. Subsequently, for $V_i < V_{DD} - |V_{fpl}|$, a high level will be produced at the output, for $V_i > V_{tn} + V_{shift}$ a low level and for $V_{DD} - |V_{fpl}| < V_i < V_{tn} + V_{shift}$ the output will retain its previous state. The aforementioned behavior is similar to a Schmitt trigger with two separate comparison levels with an upper threshold limit, $V_{T+}$, of $V_{tn} + V_{shift}$. As will be explained later, the supply voltage of the Schmitt trigger itself,

![Fig. 1. A typical configuration of a low power energy harvesting sensor node.](image)

![Fig. 2. (a) The function of a Schmitt trigger as the UVLO block of a low-power sensor node. (b) The basic concept used in the proposed ultra-low power Schmitt trigger.](image)

![Fig. 3. (a) I-V characteristics of the load placed after the rectifier. (b) Instantaneous power delivery to the load using the UVLO block.](image)
VDD, will be eventually adjusted at about $V_{Th}$ using an auxiliary rectifier. In the proposed circuit the lower threshold limit, $V_{Th}$, will be equal to $V_{tn} + V_{shift} - |V_{tp}|$. When each of the nMOS or pMOS devices are activated, they will reside in the triode region and the output can be switched to VDD or GND with less delay than devices in the subthreshold region used in conventional low-power designs. As shown below, a positive feedback further helps the output switch to its activated state.

An important challenge here is the design of a subtractor circuit which can produce the $V_{i} - V_{shift}$ level with no static power usage. As shown in Fig. 2(b), a simple nMOS diode connected device (Mnd) in series with $V_{i}$ and a parasitic capacitance of $C_{p}$ at its output, may seem to achieve the necessary function via the $V_{y} \approx V_{i} - V_{tn}$ equation expected at its source terminal. However, this subtractor will show different behavior with rising or falling inputs. A resetting switch (Mnr) can solve the aforementioned problem. When the input voltage, $V_{i}$, is increasing, the reset switch should be turned off. However, the reset switch will still impose some leakage current which is put into effective use here. The leakage current of the reset switch should be adjusted higher than the leakage current of the diode load. In this case, the subtractor output voltage will experience a drop in relation with $V_{i}$.

In Fig. 4 the resetting switch Mnr is shown while deactivated, however it still produces some subthreshold leakage current which can be modeled by $I_{0r}$. To extract the relationship of $V_{y}$ with respect to $V_{i}$, it is assumed that $V_{i}$ changes exhibit a ramp-waveform profile with time, either increasing due to the charging of the storage capacitor by the energy harnessing source or decreasing due to the discharging of the storage capacitor by the load. It is also initially assumed that in this case $V_{y}$ follows $V_{i}$ with a constant voltage shift. With these assumptions, the current on capacitor $C_{p}$ will be $C_{p,m}$ where $m$ is the slope of $V_{i}$. Thus, using subthreshold drain current equations, the relation of $V_{i}$ and $V_{y}$ can be obtained using (1) where $(W/L)$ is the corresponding MOSFET dimension ratio, $V_{th}$ is the thermal voltage, $V_{tn}$ is the threshold voltage, $I_{s}$ is a current factor and $\eta$ is a subthreshold conduction factor.

$$C_{p,m} \cdot \left( \frac{W}{L} \right)_{nd} \cdot I_{G} \cdot e^{\left( \frac{V_{y}}{\eta V_{th}} \right)} = \left( \frac{W}{L} \right)_{nd} \cdot I_{G} \cdot e^{\left( \frac{V_{i} - V_{th}}{\eta V_{th}} \right)}$$

(1)

The first term of the left hand side of equation (1) is the current on capacitor $C_{p}$ while the second term is the subthreshold leakage current of Mnr. The subthreshold leakage current of Mnr is modeled with $I_{0r}$ as shown in Fig. 4. Simplifying (1), (2) is obtained which proves that the initial assumption was correct and $V_{y}$ follows $V_{i}$ with a constant voltage shift. This constant voltage shift is however dependent on the input voltage slope, $m$.

$$V_{y} = V_{i} - V_{tn} - \eta V_{th} \ln\left( \frac{C_{p,m}}{I_{s,v}} \cdot \left( \frac{W}{L} \right)_{nd} \cdot e^{\left( \frac{V_{y}}{\eta V_{th}} \right)} \right)$$

(2)

Looking back at (1), it is observed that if $I_{0r}$ is chosen much larger than $C_{p,m}$, the first term on the left-hand side of (1) can be neglected and thus the voltage shift between $V_{i}$ and $V_{y}$ will be independent of $m$ as shown in (3).

$$V_{y} = V_{i} - \frac{\eta V_{th}}{\left( \frac{W}{L} \right)_{nd}}$$

(3)

The voltage shift, $V_{shift}$, in this case can be expressed as follows:

$$V_{shift} = \frac{\eta V_{th}}{\left( \frac{W}{L} \right)_{nd}}$$

(4)

However the power dissipated by the static current of $I_{0r}$ is expressed with (5) and large values of $I_{0r}$ will result in higher power dissipation.

$$P_{diss} = I_{0r} \cdot V_{i}$$

(5)

It should be noted that $m_{rise}$, the slope of the $V_{i}$ transient during charging of $C_{s}$ (by the energy harnessing source), is much smaller than the absolute discharge slope of $V_{i}$, $|m_{fall}|$, due to the instantaneous connection of the load. The approach used here is to choose $I_{0r}$ much larger than only $C_{p,m_{rise}}$. Subsequently when the load is connected, $V_{y}$ is discharged through another path and by activating the Mnr MOSFET. With this approach $I_{0r}$ can be kept at relatively low values to limit the static power dissipation.

The complete circuit design is shown in Fig. 5. With the proposed circuit, $V_{i}$ increases relatively slowly since it happens due to the charging of the output capacitor by the low environmental energy source. In this case $V_{y}$ follows $V_{i}$ with a constant voltage shift. When the accumulated voltage reaches the upper threshold limit, the output power switch Mns is activated and power is transferred to the load. In this phase $V_{i}$ drops rapidly with a high slope. Although in this phase the Mnd subtractor alone cannot produce a correct voltage shift between $V_{y}$ and $V_{i}$; however during this phase, the reset switch Mnr is activated to quickly return the subtractor output to its correct state.

To prevent any short circuit power dissipation a pMOS switch (Mpr) is used to disconnect the power supply path when the reset switch is activated. The final elements of the design chain are Mpr1 and Mpr2. As stated earlier, when the supply potential passes the upper threshold limit, the Schmitt trigger output should switch is a short period of time. To facilitate this transition a positive feedback is generated using Mpr1. When the Schmitt trigger output $V_{O}'$ begins to drop, Mpr1 will be activated thus helping the gate potential of Mns to further increase and to pull down the output of the Schmitt trigger.
In Fig. 8, the same parameters are investigated for the proposed circuit. The designed Schmitt trigger eliminates the short circuit currents and also the required bias currents. The only source of quiescent current is mainly the leakage current of switches in the off region. As the Figure shows, the proposed design shows a relatively constant and also considerably low quiescent current for different threshold voltage detection levels. With higher threshold voltage levels, due to the higher provided gate-source voltage, higher currents can be delivered to the output.

In Fig. 7 the same parameters are investigated for the proposed circuit. The designed Schmitt trigger eliminates the short circuit currents and also the required bias currents. The only source of quiescent current is mainly the leakage current of switches in the off region. As the Figure shows, the proposed design shows a relatively constant and also considerably low quiescent current for different threshold voltage detection levels. With higher threshold voltage levels, due to the higher provided gate-source voltage, higher currents can be delivered to the output.

As shown in Fig. 8, $V_{T+}$ of the proposed Schmitt trigger can be adjusted by changing $W/L$ ratio of diode connected MOS or placing MOS devices in series with the $V_i$ path.

To investigate the functional dependence of the proposed wake-up circuit on external factors, process and mismatch Monte Carlo evaluations and temperature sweeps were performed on the two diode circuit. Fig. 9(a) and (b) show the histogram of $V_{T+}$ and the quiescent current of the circuit using Monte Carlo simulation respectively. The number of
runs are 1000 and 500 for the two cases and conventional room temperature of 27°C is used. According to the histogram plots, \( V_{T+} \) has a mean and standard deviation of 1.74V and 0.14V respectively. This shows 68% of the chips will have a \( V_{T+} \) which changes under ±8% around the designated value. Fig. 9(b) shows the quiescent current experiences an average and sigma of 23pA and 6pA respectively.

The temperature dependence of \( V_{T+} \) and the quiescent current of the proposed circuit is also investigated in Fig. 10. It should be noted that although Fig. 10 shows \( V_{T+} \) and quiescent current changes over a temperature range of 0 to 100°C, however in the application given in this paper, the soil moisture is measured for indoor plants and greenhouses. Thus here, the conventional indoor temperature range is considered from 10 to 40°C. Judging by the obtained results over the indoor temperature variation range, \( V_{T+} \) will only experience 5% changes.

The performance of the proposed approach is also investigated using experimental evaluations. For the experimental results, discrete MOSFETs are used in the implementation. In Table I both simulation results and also experimental results of the proposed method configured with discrete MOSFETs are reported. The table investigates the effect of the number of diode-connected loads (Mnd) in the path of \( V_i \) on \( V_{T+} \). It also shows how changing \( V_{T+} \) affects other parameters much as quiescent current, maximum load current and maximum load power.

The effect of storage capacitor voltage slope of \( V_{T+} \) is also investigated in Fig. 11. Consistent with the behavior predicted in (2), the rate at which \( V_i \) increases will have a small effect on \( V_{T+} \).

Fig. 12(a) shows the signal waveform at nodes \( V_o, V_y \) and \( V_{power} \) of Fig. 5 which are acquired by oscilloscope channels 1, 2 and 3 respectively. Since the activation period of \( V_O \) is very short and can be merely seen during the voltage drop of \( V_{power} \) in Fig. 12(a), that time period is expanded in Fig. 12(b) to show how \( V_{power}, V_y \) and \( V_o \) change during the activation period.

To investigate the effectiveness of the proposed approach under low-energy conditions, the proposed wake-up circuit is used in an indoor/greenhouse soil moisture monitoring setup. Although passive tags are used extensively for the monitoring of parameters such as humidity or oxygen, but most of these sensors require a base station or observer in close proximity to sense the resulting reading [21]. Active sensors on the other hand can transmit the reading to distances far away using an active transmitter. As shown in Fig. 13(a), in a conventional active setup usually a moisture transducer is used to sense moisture and convert it to a digital code. An RF transmitter is used to transmit the digital data to the base station and finally a microcontroller is used to configure the units and also control the flow of data from the sensor to the transmitter. While some simplifications can be applied to the conventional method, the general approach tends to be power hungry. In this work, a simple circuit is used as the load of the proposed

wake-up circuit for soil moisture detection and transmission. As shown in Fig. 13(b), the load consists of a low dropout regulator and a Colpitts oscillator. The oscillator transmits an RF signal to the antenna. The oscillation frequency of the Colpitts circuit is modulated by the capacitance effect of the soil electrode. So any changes in the soil moisture will result in a frequency shift of the transmitted RF signal. Although the circuit is sensitive to external factors such as temperature, however as it will be shown in the evaluation results, for well regulated environments such as indoor rooms or greenhouses, this drawback will not be a limiting factor.

The actual prototype board used for this purpose is shown in Fig. 14. As it can be seen in the figure, the solar panel is constructed from 12, 5mm×5mm photodiodes. These p-n junctions produce energy when illuminated by light. All photodiodes are arranged in series to provide the necessary operational voltage level. Starting off from the top to bottom, after the solar panel arrangement there is the polyester main storage capacitor, the Schmitt triggers circuitry and finally the regulator and the Colpitts oscillator/transmitter. In the current picture the board electrodes are inside the soil.

Fig. 13. (a) conventional block diagram of a soil moisture detection sensor node, (b) the load used in this work for both the sensing and transmitting of soil moisture.

Fig. 14. Fabricated prototype board placed into the plant soil.

With the 10 µF low leakage polyester storage capacitor, when the voltage has reached the trip point, the wireless transmitter can be kept active for approximately 5ms duration and a short RF burst is transmitted in this time interval. In Fig. 15, the number of data bursts transmitted by the aforementioned transmitter is measured with a low-power solar panel energy source. The moisture of the soil can be assessed considering the RF frequency of the transmitted burst.

To investigate the accuracy of the proposed approach, different soil samples were prepared with specific moisture levels as described in [22]. In this procedure 35 containers were prepared by filling each with about 250mL compressed garden soil. Different water volumes were poured in every group of 5 containers. The soils were mixed well to get a homogenous sample. With this approach each container group contained a certain volumetric water content (VWC) level. The average frequency measurement of each group and also the minimum and maximum reading of the sensor at each VWC level is reported in Fig. 16. It should be noted that the reported results are normalized over the entire measurement procedure. In the proposed sensor, the normalized reading of 0 corresponds to an oscillation frequency of 27.28MHz and 1 corresponds to 26.96MHz. For the sake of comparison, the calibration curve measurement of the standard Diviner 2000 sensor [22] is also shown in Fig. 17.

The performance of the sensor was also investigated under different ambient temperatures. As shown in Fig. 17, the effect of temperature on the normalized sensor reading (oscillator frequency) is shown under different VWCs. Better temperature regulation (such as greenhouses) or temperature compensation methods can reduce the error due to this effect.

The effect of temperature on the transmission burst intervals and also burst duration is shown in Fig. 18. As the plot suggests with higher temperatures, the repetition rate will increase slightly. This result is due to the fact that at higher temperatures, $V_T$ drops slightly leading to a higher average charge current from the solar panel. Thus eventually the accumulated
charge reaches the trip point earlier. Also according to this experiment the burst duration also experiences a small change when the temperature increases. This can also be contributed to the fact that the available voltage swing to the power rail decreases at higher temperatures. Also the oscillator bias current has a small increase at higher temperatures resulting in the slight reduction of the burst signal duration.

The performance of the proposed wake-up circuit in both a simulation and also experimental setup is summarized and compared with previous methods in Table II.

![Graph showing sensor reading variation versus ambient temperature.](image1)

![Graph showing repetition and burst time drifts due to ambient temperature.](image2)

**Fig. 17.** Proposed sensor reading variation versus ambient temperature.

**Fig. 18.** Repetition and burst time drifts due to ambient temperature.

As can be seen, the proposed method outperforms previous techniques regarding the quiescent current requirements. Thus the proposed method is more appropriate for energy sources with very low output current delivery.

### V. Conclusions

Efficient energy delivery to low-power loads has been the focus of many recent researches and is an important aspect in energy harvesting circuits [23]. In this paper an ultra-low quiescent current under voltage lock out circuit was presented and successfully implemented using all-MOS devices. With the proposed circuit, low-power energy harvesters can store their energy on a low leakage capacitor and when the voltage level reaches a certain level the power can be instantaneously delivered to the electronic blocks. By avoiding any static bias current and at the same time, operating the output switches in the deep triode and cut-off region the quiescent current was significantly reduced. It was shown that the quiescent current of a discrete prototype could be as low as 200 pA, a value much smaller than those reported in previous works.

At this quiescent current, the proposed under voltage lock out circuit can drive electronic loads with powers as high as 40 mW. The proposed design approach was also compared with conventional designs of under voltage lock out techniques in the same operational conditions such as opamp-based and CMOS inverter-based. The results showed that the new approach outperforms conventional methods of UVLO design for ultra-low power energy harnessing applications.

Masoud Kargaran received the B.Sc. degree from the University of Isfahan, Isfahan, Iran, in 2017, and the M.Sc. degree from the Sharif University of Technology, Tehran, Iran, in 2019. He is currently pursuing the Ph.D. degree in electrical engineering at the Sharif University of Technology, Tehran. His current research interests include low-power sensors, high performance switching dc-dc converters and power management ICs.

Mehdi Habibi was born in Fort Worth, TX, USA, in 1981. He received the B.S., M.Sc., and Ph.D. degrees in electrical engineering from the Isfahan University of Technology, Isfahan, Iran, in 2003, 2005, and 2010, respectively. He is currently an Associate Professor with the Department of Electrical Engineering, University of Isfahan. His current research interests include CMOS sensors and low-power circuits design.

Sebastian Magierowski (M’04) received the Ph.D. degree in electrical engineering from the University of Toronto, Toronto, ON, Canada, in 2004. From 2004 to 2012, he was an Assistant Professor and an Associate Professor at the Department of Electrical and Computer Engineering, University of Calgary, Calgary, AB, Canada. He was a Faculty Member with the Department of Electrical Engineering and Computer Science, Lassonde School of Engineering, York University, Toronto, where he is currently an Associate Professor. He was with Nortel Networks, Mississauga, ON, Canada, PMC-Sierra, Sunnyvale, CA, USA, and Protolinx Corp., Toronto, where he was involved in CMOS device modeling, high-speed mixed-signal IC design, and data networks. His current research interests include analog/digital CMOS circuit design, communication systems, and biomedical instrumentation for molecular sensing and analysis.
