Compressive Periodogram Reconstruction
Using Uniform Binning

Dyonisius Dony Ariananda, Student Member, IEEE, Daniel Romero, Student Member, IEEE, and Geert Leus, Fellow, IEEE

Abstract—In this paper, two problems that show great similarities are examined. The first problem is the reconstruction of the angular-domain periodogram from spatial-domain signals received at different time indices. The second one is the reconstruction of the frequency-domain periodogram from time-domain signals received at different wireless sensors. We split the entire angular or frequency band into uniform bins. The bin size is set such that the received spectra at two frequencies or angles, whose distance is equal to or larger than the size of a bin, are uncorrelated. These problems in the two different domains lead to a similar circulant structure in the so-called coset correlation matrix. This circulant structure allows for a strong compression and a simple least-squares reconstruction method. The latter is possible under the full column rank condition of the system matrix, which can be achieved by designing the spatial or temporal sampling patterns based on a circular sparse ruler. We analyze the statistical performance of the compressively reconstructed periodogram including bias and variance. We further consider the case when the bins are so small that the received spectra at two frequencies or angles, with a spacing between them larger than the size of the bin, can still be correlated. In this case, the resulting coset correlation matrix is generally not circulant and thus a special approach is required.

Index Terms—Periodogram, averaged periodogram, compression, circulant matrix, coset correlation matrix, circular sparse ruler, multi-coset sampling, non-uniform linear array

I. INTRODUCTION

The similarity between spectral analysis problems in the spatial-angular domain and in the time-frequency domain has attracted signal processing researchers since the 1970s. Direction of arrival (DOA) estimation and frequency identification of sinusoids are examples of such similar problems examined during that period [2]. The renewed interest in spectral analysis problems, especially due to the emergence of compressive sampling, has spurred reinvestigations on this similarity because, when time-domain or spatial-domain compression is introduced, this similarity can be exploited to tackle different problems using the same algorithmic approach.

This paper focuses on both the reconstruction of the angular-domain periodogram from far-field signals received by an antenna array at different time indices (problem P1) and that of the frequency-domain periodogram from the time-domain signals received by different wireless sensors (problem P2). It further underlines the similarity between P1 and P2. Unless otherwise stated, the entire angular or frequency band is divided into uniform bins, where the size of the bins is configured such that the received spectra at two frequencies or angles, whose distance is equal to or larger than the size of a bin, are uncorrelated. In this case, the so-called coset correlation matrix will have a circulant structure, which allows the use of a periodic non-uniform linear array (non-ULA) in P1 and a multi-coset sampler in P2 in order to produce a strong compression.

Our work in P1 is motivated in part by [3], which attempts to reconstruct the angular spectrum from spatial-domain samples received by a non-ULA. Comparable works to [3] for P2 are [4] and [5], which focus on the analog signal reconstruction from its sub-Nyquist rate samples. However, the aim of [3]–[5] to reconstruct the original spectrum or signal leads to an underdetermined problem, which has a unique solution only if we add constraints on the spectrum such as a sparsity constraint. A less ambitious goal in the context of P2 is to reconstruct the power spectrum instead of the actual signal from sub-Nyquist rate samples. For wide-sense stationary (WSS) signals, this has been shown to be possible in [6] and [7] without applying a sparsity constraint on the power spectrum. Meanwhile, the work of [8] assumes the existence of a multiband signal where different bands are uncorrelated. In this case, the diagonal structure of the correlation matrix of the entries at different bands can be exploited. Note though that [8] does not focus on the strongest compression rate and uses frequency smoothing to approximate the correlation matrix computation as it relies on a single realization of the received signal. Comparable works to [7] in P1 are [9]–[11], which aim to estimate the DOA of uncorrelated point sources with fewer antennas than sensors. This is possible because for uncorrelated point sources, the spatial correlation matrix of the received signals also has a Toeplitz structure. Hence, for a given ULA, we can deactivate some antennas but still manage to estimate the spatial correlation at all lags. For example, [9] and [10] suggest to place the active antennas based on a nested or coprime array, respectively, which results in a longer virtual array called the difference co-array (which is uniform in this case). As the difference co-array generally has more antennas and a larger aperture than the actual array, the degrees of freedom are increased allowing [9] and [10] to estimate the DOA of more uncorrelated sources than sensors. In a more optimal way, a uniform difference co-array can also be obtained by the minimum redundancy array (MRA) of [12], but the nested and coprime arrays present many advantages due to their algebraic construction. MRAs have been used in [11] to estimate the DOA of more uncorrelated sources.
than sensors, or more generally, to estimate the angular-domain power spectrum.

Unlike [3], our work for P1 focuses on the angular periodogram reconstruction (similar to [11]). This allows us to have an overdetermined problem that is solvable even without a sparsity constraint on the angular domain. This is beneficial for applications that require only information about the angular periodogram and not the actual angular spectrum. Our work is also different from [9]-[11] as we do not exploit the Toeplitz structure of the spatial correlation matrix. As for P2, we focus on frequency periodogram reconstruction (unlike [4]-[5]) but we do not exploit the Toeplitz structure of the time-domain correlation matrix (unlike [7]). On the other hand, the problem handled by [8] can be considered as a special case of P2 but, unlike [8], we aim for the strongest compression rate which is achieved by exploiting the circulant structure of the coset correlation matrix and solving the minimal circular sparse ruler problem. Moreover, unlike [8], we also exploit the signals received by different sensors to estimate the correlation matrix.

Also related to P2, a cooperative compressive wideband spectrum sensing scheme for cognitive radio (CR) networks is proposed in [13]. While [13] can reduce the required sampling rate per CR, its focus on reconstructing the spectrum or the spectrum support requires a sparsity constraint on the original spectrum. Unlike [13], [14] focuses on compressively estimating the power spectrum instead of the spectrum by extending [7] for a cooperative scenario. However, while the required sampling rate per sensor can be lowered without applying a sparsity constraint on the power spectrum, the exploitation of the cross-spectra between signals at different sensors in [14] requires the knowledge of the channel state information (CSI). Our approach for P2 does not require a sparsity constraint on the original periodogram (unlike [13]) and it does not require CSI since we are not interested in the cross-spectra between samples at different sensors (unlike [14]). In [15], each wireless sensor applies a threshold on the measured average signal power after applying a random wideband filter. The threshold output is then communicated as a few bits to a fusion centre, which uses them to recover the power spectrum by generalizing the problem in the form of inequalities. The achievable compression rate with such a system is not clear though, in contrast to what we will present in this paper.

In more advanced problems, such as cyclic spectrum reconstruction from sub-Nyquist rate samples of cyclostationary signals in [16]-[18] or angular power spectrum reconstruction from signals produced by correlated sources in [19], finding a special structure in the resulting correlation matrix that can be exploited to perform compression is challenging. A similar challenge is faced in Section VII where we consider the case when we reduce the bin size such that the received spectra at two frequencies or angles with a spacing larger than the bin size can still be correlated. As the resulting coset correlation matrix in this case is generally not circular, we further develop the concepts originally introduced in [18] and [19] to solve our problem.

We now would like to summarize the advantages of our approach and highlight our contribution.

- We propose a compressive periodogram reconstruction approach, which does not rely on any sparsity constraint on the original signal or the periodogram. Moreover, it is based on a simple least-squares (LS) algorithm leading to a low complexity.
- In our approach, we also focus on the strongest possible compression that maintains the identifiability of the periodogram, which is shown to be related to a minimal circular sparse ruler.
- Our approach does not require any knowledge of the CSI.
- The statistical performance analysis of the compressively reconstructed periodogram is also provided.
- Our approach can also be modified to handle cases where the spectra in different bins are correlated.

This paper is organized as follows. The system model description (including the definition of the so-called coset correlation matrix) and the problem statement are provided in Section II. Section III discusses the spatial (for P1) or temporal (for P2) compression as well as periodogram reconstruction using LS. Here, the condition for the system matrix to have full column rank and its connection to the minimal circular sparse ruler problem are provided. Section IV shows how to approximate the expectation operation in the correlation matrix computation and summarizes the procedure to compressively estimate the periodogram. In Section V, we provide an analysis on the statistical performance of the compressively reconstructed periodogram including a bias and variance analysis. Sections VI-VII assume that the received signals at different time instants (for P1) or at different sensors (for P2) have the same statistics. To handle more general cases, we propose a multi-cluster model in Section VI which considers clusters of time indices in P1 or clusters of sensors in P2 and assumes that the signal statistics are only constant within a cluster. Another case is discussed in Section VII where the received spectra at two frequencies or angles located at different predefined bins can still be correlated. Some numerical studies are elaborated in Section VII and Section VIII provides conclusions.

Notation: Upper (lower) boldface letters are used to denote matrices (column vectors). Given an $N \times N$ matrix $\mathbf{X}$, diag($\mathbf{X}$) is an $N \times 1$ vector containing the main diagonal entries of $\mathbf{X}$. Given an $N \times 1$ vector $\mathbf{x}$, diag($\mathbf{x}$) is an $N \times N$ diagonal matrix whose diagonal entries are given by the entries of $\mathbf{x}$.

II. SYSTEM MODEL

A. Model Description and Problem Statement

We aim at estimating the following spectral representation of the power of a process $x[\hat{n}]$:

$$
P_x(\theta) = \lim_{N \to \infty} E \left\{ \frac{1}{N} \sum_{n=0}^{N-1} x[\hat{n}] e^{-j\theta \hat{n}} \right\}^2
$$

$$
= \lim_{N \to \infty} E \left\{ \frac{1}{N} \sum_{\hat{n} \in \mathbb{Z}_N} X(\hat{n})(\theta) \right\}^2. \tag{1}
$$

Here, $x[\hat{n}]$ represents either the spatial-domain process at the output of a ULA for P1 or the time-domain process sensed by a wireless sensor for P2. In addition, $X(\hat{n})(\theta)$ represents
either the value of the angular spectrum at angle $\sin^{-1}(2\theta)$ for P1 or that of the frequency spectrum at frequency $\theta$ for P2, with $\theta \in [-0.5, 0.5]$. Note from \cite{2} that, for a WSS process $x[n]$, $F_2(\theta)$ represents the power spectrum. To estimate $P_2(\theta)$ in \cite{1}, consider the $N \times 1$ complex-valued observation vectors $x_t = [x_t[0], x_t[1], \ldots, x_t[N-1]]^T$, $t = 1, 2, \ldots, \tau$, where $x_t[\tilde{n}]$ represents the output of the $(\tilde{n}+1)$-th antenna in the ULA of $\tilde{N}$ half-wavelength spaced antennas at time index $t$ for P1 or the $(\tilde{n}+1)$-th sample out of $\tilde{N}$ successive samples produced by the Nyquist-rate sampler at the $t$-th sensor for P2. To acquire an accurate Fourier interpretation, we assume a relatively large $\tilde{N}$, which is affordable for P2 and also realistic for P1, if we consider millimeter wave imaging applications where the antenna spacing is very small and thus the required aperture has to be covered by a large number of antennas \cite{3}. Denote the discrete-time Fourier transform (DTFT) of $x_t[\tilde{n}]$ by $X_t(\vartheta)$. As $X_t(\vartheta)$ at $\vartheta \in [-0.5, 0.5]$ is a replica of $X_t(\vartheta)$ at $\vartheta \in [0.5, 1)$, we can focus on $X_t(\vartheta)$ in $\vartheta \in [0, 1]$.

Next, we divide the $\tilde{N}$ uniform grid points (that is, the antennas of the ULA for P1 or the indices of the Nyquist-rate samples for P2) into $L$ non-overlapping blocks of $N$ uniform grid points. We collect all the $(n+1)$-th grid points from each of the $L$ blocks and label this collection of grid points, i.e., \{ $\tilde{n} \in \{0, 1, \ldots, \tilde{N}-1\} | \tilde{n} \mod N = n$ \}, as the $(n+1)$-th coset, with $\tilde{n} \mod N$ the remainder of the integer division $\tilde{n}/N$. In this paper, the coset index of the $(n+1)$-th coset is $n$. This procedure allows us to view the above uniform sampling as a multi-coset sampling \cite{4} with $N$ cosets. Consequently, the ULA of $\tilde{N}$ antennas in P1 can be regarded as $N$ interleaved uniform linear subarrays (ULSSs) \cite{5} (which are the cosets) of $L$ $(N\lambda/2)$-spaced antennas with $\lambda$ the wavelength, whereas the $\tilde{N}$ time-domain samples in P2 can be considered as the output of a time-domain multi-coset sampler with $L$ samples per coset. If we activate only the $(n+1)$-th coset, the spatial- or time-domain samples at index $\tilde{n}$ are given by

$$\hat{x}_{t,n}[\tilde{n}] = x_t[\tilde{n}] \sum_{l=0}^{L-1} \delta[\tilde{n}-(lN+n)], n = 0, 1, \ldots, N-1, \quad (2)$$

which can be collected into the $\tilde{N} \times 1$ vector $\hat{x}_{t,n} = [\hat{x}_{t,n}[0], \hat{x}_{t,n}[1], \ldots, \hat{x}_{t,n}[\tilde{N}-1]]^T$. Observe that $x_t = \sum_{n=0}^{N-1} \hat{x}_{t,n}$. To show the relationship between the DTFT of $\hat{x}_{t,n}[\tilde{n}]$ and that of $x_t[\tilde{n}]$, we split $\vartheta \in [0, 1)$ into $N$ equal-width bins and express the spectrum at the $(i+1)$-th bin ($i = 0, 1, \ldots, N-1$) as $X_{t,i}(\vartheta) = X_t(\vartheta + \frac{2\pi i}{N})$ with $\vartheta$ now limited to $\vartheta \in [0, 1/N)$. As either the spatial or temporal sampling rate becomes $1/N$ times the Nyquist-rate when only the $(n+1)$-th coset is activated, the DTFT of $\hat{x}_{t,n}[\tilde{n}]$, denoted by $\hat{X}_{t,n}(\vartheta)$, is the sum of $N$ aliased versions of $X_{t,i}(\vartheta)$ at different bins. This is shown for $n = 0, 1, \ldots, N-1$ as

$$\hat{X}_{t,n}(\vartheta) = \frac{1}{N} \sum_{i=0}^{N-1} X_{t,i}(\vartheta) e^{j2\pi \frac{ni}{N}}, \quad \vartheta \in [0, 1/N). \quad (3)$$

Collecting $\hat{X}_{t,n}(\vartheta)$, for $n = 0, 1, \ldots, N-1$, into the $N \times 1$ vector $\hat{x}_t(\vartheta) = [\hat{X}_{t,0}(\vartheta), \hat{X}_{t,1}(\vartheta), \ldots, \hat{X}_{t,N-1}(\vartheta)]^T$ and introducing the $N \times 1$ vector $x_t(\vartheta) = [X_{t,0}(\vartheta), X_{t,1}(\vartheta), \ldots, X_{t,N-1}(\vartheta)]^T$ allow us to write

$$x_t(\vartheta) = \mathbf{Bx}_t(\vartheta), \quad \vartheta \in [0, 1/N), \quad (4)$$

with the element of the $N \times N$ matrix $\mathbf{B}$ at the $(n+1)$-th row and the $(i+1)$-th column given by $[\mathbf{B}]_{n+1,i+1} = \frac{1}{N} e^{j2\pi \frac{ni}{N}}$.

We now assume the presence of $K$ active users, consider the model in Fig. 1 and introduce the following definition (see also Fig. 1).

**Definition 1:** We define the complex-valued zero-mean random processes $U_t^k(\vartheta)$ and $H_t^k(\vartheta)$ as

- For P1, $U_t^k(\vartheta)$ is the source signal related to the $k$-th user received at time index $t$, which can depend on the DOA $\sin^{-1}(2\theta)$ due to scattering. For P2, it is the source signal related to the $k$-th user received at sensor $\vartheta$, which can vary with frequency $\vartheta$ due to power loading.
- $H_t^k(\vartheta)$ is the related channel response for the $k$-th user at time index $t$ and DOA $\sin^{-1}(2\theta)$ for P1 or at sensor $\vartheta$ and frequency $\vartheta$ for P2.

Note from Fig. 1 that, theoretically, $U_t^k(\vartheta)$ is the only component observed by the ULA in P1 or by the sensors in P2 if no fading channel exists. Define $N_t(\vartheta)$ as the zero-mean additive white (both in $\vartheta$ and $t$) noise at DOA $\sin^{-1}(2\theta)$ and time index $t$ (for P1) or at frequency $\vartheta$ and sensor $t$ (for P2). By introducing $N_t^k(\vartheta) = N_t(\vartheta + \frac{\pi}{N})$ similarly also $H_t^k(\vartheta)$ as well as $U_t^k(\vartheta)$, we can then use Definition 1 to write $X_{t,i}(\vartheta)$ in (4) as

$$X_{t,i}(\vartheta) = \sum_{k=1}^{K} H_t^k(\vartheta) U_t^k(\vartheta) + N_t^k(\vartheta), \quad \vartheta \in [0, 1/N). \quad (5)$$

Next, let us consider the following assumption.

**Assumption 1:** $X_{t,i}(\vartheta)$ in (5) is an ergodic stochastic process along $t$.

This ergodicity assumption requires that the statistics of $X_t(\vartheta)$ in (3) do not change with $t$ (a more general case is discussed in Section VI). Hence, we can define the $N \times N$ correlation matrix of $x_t(\vartheta)$ as $\mathbf{R}_x(\vartheta) = E[x_t(\vartheta)x_t^H(\vartheta)]$, for all $t$ and $\vartheta \in [0, 1/N)$. The assumption that the statistics of $x_t(\vartheta)$ do not vary with $t$ is motivated for P1 when the signal received by the array is stationary in the time-domain. For P2, it implies that the statistics of the signal $x_t$ received by different sensors...
where we assume that the signal noise $U_t(k)(\vartheta)$, the noise $N_t(\vartheta)$, and the channel response $H_t(k)(\vartheta)$ are mutually uncorrelated. We now consider the following remark.

**Remark 1:** The diagonal of $R_x(\vartheta)$, which is given by $\{E[|X_t(i,\vartheta)|^2]\}_{i=0}^{N-1}$ and which is independent of $t$, can be related to $P_x(\vartheta)$ in (1). In practice, this expected value has to be estimated and Assumption 1 allows us to estimate $\sum_{k=1}^{K} \sum_{k'=1}^{K} E[U_{t,k}(\vartheta)U_{t,k'}^{*}(\vartheta)]E[H_{t,k}(\vartheta)H_{t,k'}^{*}(\vartheta)]$, (6)

where $\tilde{X}_t(i,\vartheta)$ is a diagonal matrix since $B$ is an inverse discrete Fourier transform (IDFT) matrix, as can be concluded from (4). Based on the aforementioned system model, we finally formulate our problem statement as follows:

**Problem Statement:** An estimate of the spectral representation of the power $P_x(\vartheta)$ in (1) (which is also the power spectrum when $x[n]$ in (1) is a WSS process), we aim to compressively reconstruct the AP of $x_t[n]$ in (3) over the index $t$, where we assume that $x_t[n]$ is ergodic along the index $t$ and that its coset correlation matrix $R_x(\vartheta)$ has a circulant structure. We discuss the compression and the reconstruction in Section 7.2 and the estimation of the correlation matrix in Section 7.3.

**B. Interpretation of AP in Remark 1**

How the AP in Remark 1 is interpreted with respect to $U_t(k)(\vartheta)$ and $H_t(k)(\vartheta)$ depends on which of the functions varies in $t$. For example, consider problem P2 and assume that only one user $k$ can occupy a given frequency $\vartheta$ at a given time and that only $H_t(k)(\vartheta)$ varies in $t$, i.e., $U_t(k)(\vartheta) = U(k)(\vartheta)$. For this example, we have from (5)

$$\frac{1}{N_T} \sum_{t=1}^{T} |X_t(\vartheta)|^2 = \frac{N}{N} \sum_{t=1}^{T} |H_t(\vartheta)|^2 + \sum_{t=1}^{T} |N_t(\vartheta)|^2 + \frac{2\text{Re}(H_t^*(\vartheta)U_t(k)(\vartheta))}{N_T},$$

(8)

where $\text{Re}(x)$ gives the real component of $x$, the first term is the classical periodogram of the user signals $\frac{|U_t(k)(\vartheta)|^2}{N}$ scaled by the averaged fading magnitude experienced at different channels $\frac{1}{N} \sum_{t=1}^{T} |H_t(k)(\vartheta)|^2$, the second term is the AP of the noises at different sensors $t$, and the last term converges to zero as $\tau$ becomes larger due to the uncorrelatedness between the noise $N_t(\vartheta)$ and the channel response $H_t(k)(\vartheta)$. The assumption that the statistics of $X_t(\vartheta)$ do not vary with $t$ (as required by Assumption 1) implies that the statistics of the fading experienced by different sensors $t$ are the same (e.g., they experience small-scale fading on top of the same path loss and shadowing).

As another example, consider problem P1 and assume that only one user $k$ can occupy a given DOA $\sin^{-1}(2\vartheta)$ at a given time and that only $U_t(k)(\vartheta)$ varies in $t$, i.e., $H_t(k)(\vartheta) = H(k)(\vartheta)$. For this example, we have from (5)

$$\frac{1}{N_T} \sum_{t=1}^{T} |X_t(\vartheta)|^2 = \frac{|H(k)(\vartheta)|^2}{N} \sum_{t=1}^{T} |U_t(k)(\vartheta)|^2 + \sum_{t=1}^{T} |N_t(\vartheta)|^2 + \frac{2\text{Re}(U_t^*(k)(\vartheta)H(k)(\vartheta)N_t^*(\vartheta))}{N_T},$$

(9)

where the first term is the angular-domain AP of the user signals $\frac{1}{N_T} \sum_{t=1}^{T} |U_t(k)(\vartheta)|^2$ scaled by the magnitude of the time-invariant channel angular response $|H(k)(\vartheta)|^2$, the second term is the angular-domain AP of the noise, and the last term again converges to zero as $\tau$ becomes larger due to the uncorrelatedness between $N_t(\vartheta)$ and $U_t(k)(\vartheta)$.
III. COMPRESSION AND RECONSTRUCTION

A. Spatial or Temporal Compression

As \( R_\vec{x}(\theta) \) in (9) is a circulant matrix, it is possible to condense its entries into an \( N \times 1 \) vector \( r_\vec{x}(\theta) = [r_\vec{x}(\theta, 0), r_\vec{x}(\theta, 1), \ldots, r_\vec{x}(\theta, N - 1)]^T \) with \( r_\vec{x}(\theta, (n - n') \mod N) = E[\hat{X}_{t,n}(\theta), \hat{X}_{t,n'}(\theta)] \). We can then relate \( r_\vec{x}(\theta) \) to \( R_\vec{x}(\theta) \) as

\[
\text{vec}(R_\vec{x}(\theta)) = T r_\vec{x}(\theta), \quad \theta \in [0, 1/N),
\]

where \( T \) is an \( N^2 \times N \) repetition matrix whose \((q + 1)\)-th row is given by the \((q - \lfloor \frac{q}{N} \rfloor) \mod N + 1\)-th row of the \( N \times N \) identity matrix \( I_N \) and \( \text{vec}(\cdot) \) is the operator that stacks all columns of a matrix into one column vector. The possibility to condense the \( N^2 \) entries of \( R_\vec{x}(\theta) \) into the \( N \) entries of \( r_\vec{x}(\theta) \) facilitates compression by performing a spatial- or time-domain non-uniform periodic sampling (similar to [5]), in which only \( M < N \) cosets are activated. Here, we use the set \( M = \{n_0, n_1, \ldots, n_{M-1}\} \), with \( 0 \leq n_0 < n_1 < \cdots < n_{M-1} \leq N - 1 \), to indicate the indices of the \( M \) active cosets. All values of \( \hat{X}_{t,n}(\theta) \) in (8) are then collected and their corresponding DTFT \( \hat{X}_{t,n}(\theta) \) in (3) is computed for all \( n \in M \). Stacking \( \{\hat{X}_{t,n}(\theta)\}_{n \in M} \) into the \( M \times 1 \) vector \( \vec{y}_t(\theta) = \left[\hat{X}_{t,n_0}(\theta), \hat{X}_{t,n_1}(\theta), \ldots, \hat{X}_{t,n_{M-1}}(\theta)\right]^T \) allows us to relate \( \vec{y}_t(\theta) \) to \( \vec{x}_t(\theta) \) in (4) as

\[
\vec{y}_t(\theta) = C \vec{x}_t(\theta), \quad \theta \in [0, 1/N),
\]

where \( C \) is an \( M \times N \) selection matrix whose rows are selected from the rows of \( I_N \) based on \( M \). Since \( C \) is real, the \( M \times M \) correlation matrix of \( \vec{y}_t(\theta) \), for \( \theta \in [0, 1/N) \), can be written as

\[
R_{\vec{y}}(\theta) = E[\vec{y}_t(\theta)\vec{y}_t^H(\theta)] = CR_{\vec{x}}(\theta)C^T.
\]

We then take (10) into account, cascade all columns of \( R_{\vec{y}}(\theta) \) into a column vector \( \text{vec}(R_{\vec{y}}(\theta)) \), and write

\[
\text{vec}(R_{\vec{y}}(\theta)) = R_c \vec{r}_x(\theta), \quad \theta \in [0, 1/N),
\]

where \( R_c = (C \otimes C)T \) is a real \( M^2 \times N \) matrix and \( \otimes \) denotes the Kronecker product operation.

B. Reconstruction

If \( R_c \) in (13) is a tall matrix (\( M^2 \geq N \)), which is possible despite \( M < N \), and if it has full column rank, \( r_\vec{x}(\theta) \) in (13) can be reconstructed from \( \text{vec}(R_{\vec{y}}(\theta)) \) using LS for all \( \theta \in [0, 1/N) \). In addition, as long as the identifiability of \( r_\vec{x}(\theta) \) in (13) is preserved, we can also consider estimators other than LS (such as in [20]). To formulate a necessary and sufficient condition for the identifiability of \( r_\vec{x}(\theta) \) in (13) from \( \text{vec}(R_{\vec{y}}(\theta)) \), let us review the concept of a circular sparse ruler defined in [21].

Definition 2: A circular sparse ruler of length \( N - 1 \) is a set \( K \subset \{0, 1, \ldots, N - 1\} \) for which \( \Omega(K) = \{(\kappa - \kappa') \mod N | \kappa, \kappa' \in K\} = \{0, 1, \ldots, N - 1\} \). We call it minimal if there is no other circular sparse ruler of length \( N - 1 \) with fewer elements.

Detailed information about circular sparse rulers can be found in [21]. We can then use this concept to formulate the following theorem whose proof is available in [1].

Theorem 1: \( r_\vec{x}(\theta) \) in (13) is identifiable from \( \text{vec}(R_{\vec{y}}(\theta)) \), i.e., \( R_c \) has full column rank, if and only if \( M \) is a circular sparse ruler; i.e., \( \Omega(M) = \{0, 1, \ldots, N - 1\} \). When this is satisfied, \( R_c \) contains all rows of \( I_N \).

Our goal is to obtain the strongest possible compression rate \( M/N \) preserving the identifiability. This is achieved by minimizing the cardinality of the set \( M \), \( |M| = M \), under the condition that \( \Omega(M) = \{0, 1, \ldots, N - 1\} \). This leads to a length-(\( N - 1 \)) minimal circular sparse ruler problem, which can be written as

\[
\min_{M} |M| \text{ s.t. } \Omega(M) = \{0, 1, \ldots, N - 1\}.
\]

Solving (14) minimizes the compression rate \( M/N \) while maintaining the identifiability of \( r_\vec{x}(\theta) \) in (13).

Recall that, for \( P_1 \), \( M \) indicates the indices of the \( M < N \) active ULSs in our ULA, which will be referred to as the underlying array. Therefore, we have a periodic non-ULA of active antennas and \( M \) governs the location of the active antennas in each spatial period. When \( M \) is a solution of the minimal length-(\( N - 1 \)) circular sparse ruler problem in (14), we can label the resulting non-ULA of active antennas as a periodic circular MRA and each of its spatial periods as a circular MRA. Similarly for \( P_2 \), we can label the non-uniform sampling in each temporal period as minimal circular sparse ruler sampling and the entire periodic non-uniform sampling as periodic minimal circular sparse ruler sampling if the indices of the \( M < N \) active cosets are given by the solution of (14).

Once \( r_\vec{x}(\theta) \) is reconstructed from \( \text{vec}(R_{\vec{y}}(\theta)) \) in (13) using LS for \( \theta \in [0, 1/N) \), we can use (10) to compute \( R_{\vec{x}}(\theta) \) from \( r_\vec{x}(\theta) \) and (7) to compute \( R_{\vec{x}}(\theta) \) from \( R_\vec{x}(\theta) \) as \( R_{\vec{x}}(\theta) = N^2 B^H R_{\vec{x}}(\theta)B \). As we have \( \text{diag}(R_{\vec{x}}(\theta)) = [E[|X_{t,0}(\theta)|^2], E[|X_{t,1}(\theta)|^2], \ldots, E[|X_{t,N-1}(\theta)|^2]]^T \) with \( \theta \in [0, 1/N) \), reconstructing \( \text{diag}(R_{\vec{x}}(\theta)) \) for all \( \theta \in [0, 1/N) \) gives \( E[|X_{t,1}(\theta)|^2] \) for all \( \theta \in [0, 1] \).

IV. CORRELATION MATRIX ESTIMATION

In practice, the expectation in (12) must be approximated. Here, we propose to approximate the expectation in (12) with the sample average over different time indices \( t \) for \( P_1 \) or sensors indices \( t \) for \( P_2 \), i.e.,

\[
\hat{R}_{\vec{y}}(\theta) = \frac{1}{\tau} \sum_{t=1}^{\tau} \vec{y}_t(\theta)\vec{y}_t^H(\theta), \quad \theta \in [0, 1/N),
\]

where we recall that \( \tau \) is either the total number of time indices or sensors from which the observations are collected. Observe that the \( M \times M \) matrix \( \hat{R}_{\vec{y}}(\theta) \) is an unbiased estimate of \( R_{\vec{y}}(\theta) \) in (15). It is also a consistent estimate if Assumption 1 holds. We can then apply LS reconstruction on \( R_{\vec{y}}(\theta) \) in (15) instead of \( R_{\vec{y}}(\theta) \) in (13). As a result, the procedure to compressively reconstruct the AP of \( x_t[n] \) in (2) over the index \( t \) can be listed as

1) For \( t = 1, 2, \ldots, \tau \), collect all values of \( \bar{x}_{t,n}[n] \) in (2) and compute their corresponding DTFT \( \hat{X}_{t,n}(\theta) \) in (3) for all \( n \in M \). We use them to form \( \vec{y}_t(\theta) \) in (11).
2) Compute \( \hat{R}_{\vec{y}}(\theta) \), for \( \theta \in [0, 1/N) \), using (15).
3) Based on (13) and for \( \theta \in [0, 1/N) \), we apply LS reconstruction on \( \hat{R}_{\vec{y}}(\theta) \) leading to
\( \hat{r}_{x,LS}(\theta) = (R_c^T R_c)^{-1} R_c^T \text{vec}(\hat{R}_y(\theta)). \) (16)

4. Based on (10) and (7), for \( \theta \in [0, 1/N) \), we compute
\[ \text{vec}(\hat{r}_{x,LS}(\theta)) = T \hat{r}_{x,LS}(\theta) \]
and
\[ \hat{R}_{x,LS}(\theta) = N^2 B^H \hat{r}_{x,LS}(\theta) B. \] (17)

5. Note that the \((i+1)\)-th diagonal element of \( \hat{R}_{x,LS}(\theta) \), i.e., \([\text{diag}(\hat{R}_{x,LS}(\theta))]_{i+1} \) is the LS estimate of the \((i+1)\)-th diagonal element of \( R_x(\theta) \), which according to Remark 1 is given by \( E[X_t,i(\theta)]^2 \). Based on the definition of AP in Remark 1 and considering (15), we can then formulate the compressive AP (CAP) of \( x_i[n] \) in (2) over the index \( t \) as
\[ \hat{P}_{x,LS}(\theta + i/N) = \frac{1}{N} \text{diag}(\hat{R}_{x,LS}(\theta))_{i+1}, \] (18)
for \( \theta \in [0, 1/N) \) and \( i = 0, 1, \ldots, N - 1 \).

Note that, when reconstructing the CAP \( \hat{P}_{x,LS}(\theta) \) in (18), we introduce additional errors with respect to the AP \( \frac{1}{N^2} \sum_{i=1}^{N} |X_t(i)|^2 \) in Remark 1 (including the ones in (3) and (9)). This error emerges during the compression and the LS operation in (10). This issue will be discussed up to some extent in the next section.

**V. PERFORMANCE ANALYSIS**

**A. Bias Analysis**

The bias analysis of the CAP \( \hat{P}_{x,LS}(\theta) \) in (18) with respect to \( P_{x}(\theta) \) in (11) is given by the following theorem whose proof is available in Appendix A.

**Theorem 2:** For \( \theta \in [0, 1/N) \), the CAP \( \hat{P}_{x,LS}(\theta) \) in (18) is an asymptotically (with respect to \( N \)) unbiased estimate of \( P_x(\theta) \) in (11).

**B. Variance Analysis**

By a variance analysis, the covariance between the elements of \( \hat{R}_y(\theta) \) in (15) is not trivial for a general signal \( x_i[n] \) in (2) as it involves the computation of fourth order moments. To get a useful insight, let us consider the case when the distribution of \( x_i[n] \) in (2) (and thus also \( X_{t,i}(\theta) \) in (19)) is jointly Gaussian. In this case, the fourth order moment computation is simplified by using the results in (22). If \( x_1, x_2, x_3, \) and \( x_4 \) are jointly (real or complex) Gaussian random variables, we have
\[ E[x_1 x_2 x_3 x_4] = E[x_1 x_2] E[x_3 x_4] + E[x_1 x_3] E[x_2 x_4] + E[x_1 x_4] E[x_2 x_3] - 2E[x_1] E[x_2] E[x_3] E[x_4]. \]

Using this result, the covariance between the elements of \( \hat{R}_y(\theta) \) in (19), when \( x_i[n] \) in (2) is jointly Gaussian, can be shown to be
\[ \text{Cov}[\hat{R}_y(\theta)]_{m+1,m'+1} = \frac{1}{N^4} \sum_{i=1}^{\tau} \sum_{i'=1}^{\tau} e^{j2\pi(n_m-n_{m'})(i-i')}, \] (19)
for \( \theta \in [0, 1/N) \) and \( m, m', a, a' = 0, 1, \ldots, M - 1 \), where we also assume that \( x_i[n] \) in (2) has zero mean (see Definition 1).

Under the above assumptions, we introduce the \( M^2 \times M^2 \) covariance matrix \( \Sigma_{R_y}(\theta) = E[\text{vec}(\hat{R}_y(\theta)) \text{vec}(\hat{R}_y(\theta))^H] - E[\text{vec}(\hat{R}_y(\theta))] E[\text{vec}(\hat{R}_y(\theta))^H] \), whose entry at the \((Mm'+1, Mm)+1\)-th row and the \((Mm+a+1, Mm+a+1)\)-th column is given by
\[ \text{Cov}[\hat{R}_y(\theta)]_{m+m'+1}, \] (20)
and use (17) to introduce \( \Sigma_{R_y,LS}(\theta) \) as the \( N^2 \times N^2 \) covariance matrix of \( \text{vec}(\hat{R}_{x,LS}(\theta)) \), which can be written as
\[ \Sigma_{R_y,LS}(\theta) = N^4 (B^H \otimes B^H) \Sigma_{R_y}(\theta) (B^* \otimes B), \] (21)
for \( \theta \in [0, 1/N) \). Recall from (18) that the CAP \( \hat{P}_{x,LS}(\theta + i/N) \), for \( \theta \in [0, 1/N) \) and \( i = 0, 1, \ldots, N - 1 \), is given by
\[ \frac{N}{N^2} [\hat{R}_{x,LS}(\theta)]_{i+1,i+1}. \] (22)

It is then trivial to show that the variance of \( \hat{P}_{x,LS}(\theta + i/N) \) is given by
\[ \text{Var}[\hat{P}_{x,LS}(\theta + i/N)] = \frac{1}{N^2} [\Sigma_{R_y,LS}(\theta)]_{N+i+1,N+i+1}, \] (23)
for \( \theta \in [0, 1/N) \) and \( i = 0, 1, \ldots, N - 1 \).

To get even more insight into this result, we consider a specific case in the next proposition whose proof is provided in Appendix B.

**Proposition 1:** When \( x_i[n] \) in (2) contains only circular complex zero-mean Gaussian i.i.d. noise with variance \( \sigma^2 \), the covariance between the elements of \( \hat{R}_y(\theta) \) in (19), for \( \theta \in [0, 1/N) \), is given by
\[ \text{Cov}[\hat{R}_y(\theta)]_{m+m'+1, [\hat{R}_y(\theta)]_{a+a'+1} = \frac{L^2 \sigma^4}{\tau} \delta[m-a] \delta[m'-a'], \] (24)
where \( \delta[m-a] \delta[m'-a'] \) is the Kronecker delta function.

It is clear from (24) that \( \Sigma_{R_y,LS}(\theta) \) in (21) is then a diagonal matrix and we can find from (22) that \( \text{Var}[\hat{P}_{x,LS}(\theta)] \propto \sigma^4 \) or \( \text{Var}[\hat{P}_{x,LS}(\theta)] \propto P_x^2(\theta) \). This observation can be related to a similar result found for the conventional periodogram estimate of white Gaussian noise sampled at Nyquist rate in (23).

**C. Effect of the Compression Rate on the Variance**

In this section, we focus on the impact of the compression rate \( M/N \) on the variance analysis by first defining an \( N \times 1 \) vector \( w = [w[0], w[1], \ldots, w[N-1]]^T \) containing binary entries, with \( w[n] = 1 \) if \( n \in M \) (i.e., the coset with index \( n \) is one of the \( M \) activated cosets) and \( w[n] = 0 \) if \( n \notin M \). In other words, the entries of \( w \) indicate which \( M \) out of the \( N \) cosets are activated. Let us then focus on (16) and consider the following remark.

**Remark 3:** The same argument that leads to Theorem 1 (see
Lemma 1 in [11] shows that the rows of $R_x$ are given by the \((g-f) \mod N + 1\)-th rows of $I_N$, for all $f, g \in M$. As a result, $R_x^T R_x$ is an $N \times N$ diagonal matrix. Denote the value of the $\kappa$-th diagonal element of $R_x^T R_x$ as $\gamma_\kappa$. We can then show that $\gamma_\kappa$ is given by

$$\gamma_\kappa = \sum_{n=0}^{N-1} w[(n+\kappa-1) \mod N] w[n], \quad \kappa = 1, 2, \ldots, N. \quad (25)$$

The proof of (25) is available in Appendix D. Using (25), we can also show that $\gamma_\kappa$ gives the number of times the $\kappa$-th row of $I_N$ appears in $R_x$, i.e., the number of pairs $(g, f)$ that lead to $(g-f) \mod N + 1 = \kappa$. As we have $|M| = M$, we can find that $\gamma_\kappa = M^2 - \gamma_1 = M$.

Using Remark 3, we then formulate the following theorem whose proof is available in Appendix D.

Theorem 3: When $x_t[n]$ in (2) contains only circular complex zero-mean Gaussian i.i.d. noise with variance $\sigma^2$, the variance of the CAP $\hat{P}_{x,LS}(\theta + \frac{\delta}{N})$ in (23), for $\theta \in [0, 1/N)$ and $i = 0, 1, \ldots, N - 1$, is given by

$$\text{Var}[\hat{P}_{x,LS}(\theta + \frac{i}{N})] = \frac{\sigma^4}{M^2} + \frac{\sigma^4}{\tau} \sum_{n=1}^{N-1} \frac{1}{\gamma_{n+1}}. \quad (26)$$

Note how (26) relates $M$ and $N$ to $\text{Var}[\hat{P}_{x,LS}(\theta)]$ for circular complex zero-mean Gaussian i.i.d. noise and $\theta \in [0, 1)$. Recalling from Remark 3 that $\sum_{n=1}^{N} \gamma_{n+1} = M^2 - \gamma_1 = M$, we can find that, for a given $N$, a stronger compression rate (smaller $M/N$) tends to lead to a larger $\text{Var}[\hat{P}_{x,LS}(\theta)]$. Based on (25) and (26), it is of interest to find the binary values of $\{w[n]\}_{n=0}^{N-1}$ (or equivalently the cosets $n_m \in M$) that minimize $\text{Var}[\hat{P}_{x,LS}(\theta)]$ for a given $M$. This will generally lead to a non-convex optimization problem, which is difficult to solve, although it is clear that the solution will force the values of $\{\gamma_{n+1}\}_{n=0}^{N-1}$ to be as equal as possible. Alternatively, we can also put a constraint on $\text{Var}[\hat{P}_{x,LS}(\theta + \frac{i}{N})]$ in (26) and find the binary values $\{w[n]\}_{n=0}^{N-1}$ that minimize the compression rate $M/N$. This however, will again lead to a non-convex optimization problem that is difficult to solve. Note that, although finding $w$ that minimizes $M/N$ for a given $\text{Var}[\hat{P}_{x,LS}(\theta)]$ in (26) or the one that minimizes $\text{Var}[\hat{P}_{x,LS}(\theta)]$ for a given $M/N$ is not trivial, the solution will always have to satisfy the identifiability condition in Theorem 1. This is because we can show that if the identifiability condition is not satisfied, some $\gamma_n$ in (26) will be zero and thus $\text{Var}[\hat{P}_{x,LS}(\theta)]$ in (26) will have an infinite value.

The analysis of the effect of $M/N$ on $\text{Var}[\hat{P}_{x,LS}(\theta)]$ for a general Gaussian signal $x_t[n]$, however, is difficult since it is clear from (26) that $\text{Var}[\hat{P}_{x,LS}(\theta)]$ for this case depends on the unknown statistics of $x_t[n]$. This is also true for a more general signal.

D. Asymptotic Performance Analysis

We now discuss the asymptotic behaviour of the performance of the CAP $\hat{P}_{x,LS}(\theta)$. We start by noting that Assumption 1 ensures that $\hat{R}_y(\theta)$ in (15) is a consistent estimate of $R_y(\theta)$ in (15). i.e., $\hat{R}_y(\theta)$ converges to $R_y(\theta)$ as $\tau$ approaches $\infty$. As it is clear from (16) and (17) that $R_{x,LS}(\theta)$ is linearly related to $R_y(\theta)$, it is easy to show that $R_{x,LS}(\theta)$ converges to $R_x(\theta)$ in (2) as $\tau$ approaches $\infty$. This implies that the CAP $\hat{P}_{x,LS}(\theta + \frac{\delta}{N})$ in (15) also converges to $\frac{1}{\tau} \text{E}[\text{diag}(R_x(\theta))_{i=t+1}^N]$, for $\theta \in [0, 1/N)$ and $i = 0, 1, \ldots, N - 1$, as $\tau$ approaches $\infty$. Since $x_t[n]$ in (2) is an observation of the true process $x_t[n]$ in (1), $\hat{P}_{x,LS}(\theta)$ will converge to $P_x(\theta)$ in (1) if both $\tau$ and $N$ (or $L$ for a fixed $N$) approach $\infty$.

E. Complexity Analysis

Let us now compare the complexity of our CAP approach with an existing state-of-the-art approach to tackle similar problems. We compare our CAP approach with a method that reconstructs $X_1(\theta)$ (instead of the periodogram), for $\theta \in [0, 1)$ and all $t = 1, 2, \ldots, \tau$, from compressive measurements. The reconstruction of $\{X_t(\theta)\}_{t=1}^\tau$, for $\theta \in [0, 1/N)$, is performed by reconstructing $\{x_t(\theta)\}_{t=1}^\tau$ in (4) from $\{y_t(\theta)\}_{t=1}^\tau$ in (11), for $\theta \in [0, 1/N)$, using the Regularized M-FOCUSS (RM-FOCUSS) approach of (24). We then use the reconstructed $\{x_t(\theta)\}_{t=1}^\tau$, for $\theta \in [0, 1/N)$, either to compute the periodogram or to compute the energy at $\theta \in [0, 1)$ and to detect the existence of active user signals. Note that RM-FOCUS is designed to treat $\{y_t(\theta)\}_{t=1}^\tau$, for each $\theta$, as multiple measurement vectors (MMVs) and exploit the assumed joint sparsity structure in $\{x_t(\theta)\}_{t=1}^\tau$.

Table II summarizes the computational complexity of CAP and RM-FOCUSS (see [24] for more details). Note that Table II only describes the computational complexity of RM-FOCUSS for a single iteration. The number of RM-FOCUSS iterations depends on the convergence criterion parameter (labeled as $\delta$ in [24]). Hence, we can argue that our CAP approach is simpler than RM-FOCUSS. Moreover, in RM-FOCUSS, we also need to determine a proper regularization parameter (labeled as $\lambda$ in [24]), which is generally not a trivial task. Note that we also compare the detection performance of the two methods in the sixth experiment of Section VII-A. Note that the reconstruction of $x_t(\theta)$ from $y_t(\theta)$ is also considered in [15] but it only considers the single-sensor case.

VI. MULTI-CLUSTER SCENARIO

Recall that the ergodicity assumption on $x_t(\theta)$ in Assumption 1 requires the statistics of $x_t(\theta)$ to be the same along index $t$. Let us now consider the case where we have $D$ clusters of $\tau$ time indices in $P_1$ or of $\tau$ sensors in $P_2$ such that $x_t(\theta)$ is ergodic and its statistics do not change only along index $t$ within a cluster. We can then consider Assumption 1 and the resulting case considered in Sections III-V as a special case of this multi-cluster scenario with $D = 1$. We introduce the correlation matrix of $x_t(\theta)$ and $y_t(\theta)$ for all indices $t$ belonging to cluster $d$ as $R_{x,d}(\theta)$ and $R_{y,d}(\theta)$, respectively, with $d = 0, 1, \ldots, D - 1$. We can then repeat all the steps of Sections III-V for each cluster. More precisely, we can follow (15) and define the estimate of $R_{y,d}(\theta)$ as $\hat{R}_{y,d}(\theta)$, which is computed by averaging the outer-product of $\hat{y}_t(\theta)$ over indices $t$ belonging to cluster $d$. Then, we apply (16)–(18) on $\hat{R}_{y,d}(\theta)$ to obtain $R_{x,d}(\theta)$ and the CAP for cluster $d$. 
TABLE I

COMPUTATIONAL COMPLEXITY OF THE CAP APPROACH AND THE RM-FOCUSS OF \[24\] FOR A GIVEN FREQUENCY POINT \(\vartheta \in [0, 1/N]\).

| CAP approach | Computational steps | Computational complexity |
|--------------|--------------------|-------------------------|
| Computation of \(R_x(\vartheta)\) in \[15\] | \(O(M^2\tau)\) |
| Computation of \(R_y^T R_x\) in \[16\] | \(O(N^2M^2)\) |
| Inversion of \(R_y^T R_x\) in \[16\] | \(O(N^2)\) |
| Multiplication between \(R_x(\vartheta)\) and \(R_y^T \text{vec}(R_x(\vartheta))\) in \[15\] | \(O(N^2M^2)\) + \(O(NM^2)\) |
| Computation of \(\hat{B}\) (recall that \(B\) in \[14\] is an IDFT matrix) | \(O(N \log N)\) |
| Total | \(O(N^2M^2) + O(M^2\tau) + O(NM^2) + O(NM\tau)\) |

| RM-FOCUSS of \[24\] (per iteration) | Computational steps | Computational complexity |
|---------------------------------|--------------------|-------------------------|
| Computation of \(\ell_2\)-norm of each row of an \(N \times \tau\) matrix | \(O(N\tau)\) |
| Multiplication between an \(M \times N\) matrix and an \(N \times \tau\) matrix | \(O(N^2M)\) |
| Multiplication between an \(M \times N\) matrix and an \(M \times \tau\) matrix | \(O(MN\tau)\) |
| Inversion of an \(M \times M\) matrix and an \(M \times \tau\) matrix | \(O(M\tau)\) |
| Multiplication between an \(N \times M\) matrix and an \(M \times \tau\) matrix | \(O(NM\tau)\) |
| Multiplication between an \(N \times M\) matrix and an \(N \times \tau\) matrix | \(O(N^2\tau)\) |
| Total | \(O(N^2M) + O(M^2\tau) + O(NM^2) + O(NM\tau)\) |

\(\hat{P}_{x,L,S,d}(\vartheta)\). Also note that the bias and variance analysis in Section \[V\] is also valid for each cluster in this section.

We might then be interested in the averaged statistics over the clusters, i.e., \(\frac{1}{D} \sum_{d=0}^{D-1} R_x(\vartheta)\). Since \(\frac{1}{D} \sum_{d=0}^{D-1} \hat{R}_{x,d}(\vartheta)\) is a consistent estimate of \(\frac{1}{D} \sum_{d=0}^{D-1} R_x(\vartheta)\), we can then consider the resulting \(\frac{1}{D} \sum_{d=0}^{D-1} R_x, L.S, d(\vartheta)\) as a valid estimate of \(\frac{1}{D} \sum_{d=0}^{D-1} R_x(\vartheta)\). Defining the theoretical spectral representation of the power at cluster \(d\) as \(P_x(\vartheta)\), we can then apply Theorem 2 for each cluster to conclude that \(\frac{1}{D} \sum_{d=0}^{D-1} \hat{P}_{x,L,S,d}(\vartheta)\) is an asymptotically (with respect to \(N\)) unbiased estimate of \(\frac{1}{D} \sum_{d=0}^{D-1} P_x(\vartheta)\). This multi-cluster scenario is of interest for P2 when we have clusters of wireless sensors sensing user signals where the signal from each user experiences the same fading statistics (the same path loss and shadowing) on its way towards the sensors belonging to the same cluster. However, the fading statistics experienced by the signal between the user location and different clusters are not the same. For P1, the multi-cluster scenario implies that the array sensing time can be grouped into multiple clusters of time indices where the signal statistics do not vary along the time within the cluster but they vary across different clusters.

VIII. CORRELATED BINS

When the bin size is reduced by increasing \(N\) in \[3\], the received spectra at two frequencies or angles, which are separated by more than the size of the bin, might still be correlated. In this case, \(R_x(\vartheta)\) and \(\tilde{R}_x(\vartheta)\) in \[7\] are respectively not a diagonal and circulant matrix anymore, and the temporal and spatial compression of Section \[II-A\] cannot be performed without violating the identifiability of \(r_x(\vartheta)\) in \[13\]. This section proposes a solution when this situation occurs under Assumption 1 and the single-cluster scenario (it does not apply to the multi-cluster scenario of Section \[VI\]).

Let us organize \(\tau\) indices \(t\) into several groups and write as \(t = pZ + z + 1\) with \(p = 0, 1, \ldots, P-1\) and \(z = 0, 1, \ldots, Z-1\), where \(Z\) and \(P\) represent the total number of groups and the number of indices belonging to a group, respectively. Writing \(\tilde{y}_x(\vartheta)\) and \(x_z(\vartheta)\) at \(t = pZ + z + 1\) as \(\tilde{y}_{p,z}(\vartheta)\) and \(\tilde{x}_{p,z}(\vartheta)\), we can introduce for each \(z\) a compression similar to \[11\] as

\[
\tilde{y}_{p,z}(\vartheta) = C_z \tilde{x}_{p,z}(\vartheta), \quad \vartheta \in [0, 1/N],
\]

\[
(27)
\]

where \(C_z\) is the \(M \times N\) selection matrix for the \(z\)-th group of indices whose rows are also selected from the rows of \(I_N\). Next, we compute the correlation matrix of \(\tilde{y}_{p,z}(\vartheta)\) in \[27\], i.e., \(R_{\tilde{y}_{p,z}}(\vartheta) = E[\tilde{y}_{p,z}(\vartheta)\tilde{y}_{p,z}^H(\vartheta)]\), for \(z = 0, 1, \ldots, Z-1\), as

\[
R_{\tilde{y}_{p,z}}(\vartheta) = C_z E[\tilde{x}_{p,z}(\vartheta)\tilde{x}_{p,z}^H(\vartheta)]C_z^T = C_z R_x(\vartheta)C_z^T,
\]

\[
(28)
\]

with \(R_x(\vartheta) = E[\tilde{x}_{p,z}(\vartheta)\tilde{x}_{p,z}^H(\vartheta)]\), for all \(p, z\), as Assumption 1 requires that the statistics of \(x_z(\vartheta)\) do not vary with \(t\).

Let us interpret the above model for problems P1 and P2. For P1, \[27\] implies that we split the array scanning time \(T\) into \(P\) scanning periods, each of which consists of \(Z\) time slots. It is clear from \[27\] that, in different time slots per scanning period, different sets of \(M\) ULSSs out of \(N\) available ULSSs in the underlyingULA are activated leading to a dynamic linear array (DLA). This DLA model has actually been introduced in \[19\] though it is originally designed to estimate the DOA of more sources than active antennas, where the sources can be highly correlated. Here, the indices of the selected rows of \(I_N\) used to form \(C_z\) correspond to the indices of the active ULSSs at time slot \(z\), the set of \(M\) active ULSSs in a given time slot \(z\) is the same across different scanning periods, and the number of received time samples per antenna in a time slot is one. Fig. 4 shows an example of this DLA model for P2.

Since it turns out that the mathematical model in \[19\] is applicable for both P1 and P2, we can then follow \[19\].
Fig. 3. The model for problem P2 when the bins are correlated with $M = 3$, $N = 5$, $P = 2$, and $Z = 4$. For simplicity, we illustrate the multi-coset sampling as a Nyquist-rate sampling followed by a multiplexer and a switch that performs sample selection based on $C_z$. Sensors in the same group have the same colour. For example, sensors in group $z = 0$ collect the samples at the cosets with coset indices $0, 1,$ and $2$.

rewrite (28) for $z = 0, 1, \ldots, Z - 1$ as

$$\mathbf{r}_{y_z}(\vartheta) = \mathbf{vec}(\mathbf{R}_{y_z}(\vartheta)) = (C_z \otimes C_z)\mathbf{vec}(\mathbf{R}_x(\vartheta)),$$

combine $\mathbf{r}_{y_z}(\vartheta)$ for all $z$ into $\mathbf{r}_{y}(\vartheta) = [\mathbf{r}_{y_0}^T(\vartheta), \mathbf{r}_{y_1}^T(\vartheta), \ldots, \mathbf{r}_{y_{Z-1}}^T(\vartheta)]^T$, and write $\mathbf{r}_{y}(\vartheta)$ as

$$\mathbf{r}_{y}(\vartheta) = \Psi \mathbf{vec}(\mathbf{R}_x(\vartheta)),$$

with $\Psi$ an $M^2Z \times N^2$ matrix given by

$$\Psi = [(C_0 \otimes C_0)^T, \ldots, (C_{Z-1} \otimes C_{Z-1})^T]^T, \quad (30)$$

We can solve for $\mathbf{vec}(\mathbf{R}_x(\vartheta))$ from $\mathbf{r}_{y}(\vartheta)$ in (29) using LS if $\Psi$ in (30) has full column rank. It has been shown in [19] that $\Psi$ has full column rank if and only if each possible pair of two different rows of $\mathbf{I}_N$ is simultaneously used in at least one of the matrices $\{C_z\}_{z=0}^{Z-1}$. In P1, this implies that each possible combination of two ULSs in the underlying ULA should be active in at least one time slot per scanning period. In P2, this implies that each possible pair of two cosets (out of $N$ possible cosets) should be simultaneously used by at least one group of sensors. Observe how the DLA model in Fig. 2 and the model in Fig. 3 satisfy this requirement. Once $\mathbf{vec}(\mathbf{R}_x(\vartheta))$ is reconstructed, we follow the procedure in Section III-B to reconstruct $\mathbf{R}_x(\vartheta) = E[\mathbf{x}_{p,z}(\vartheta)\mathbf{x}_{p,z}^H(\vartheta)]$ from $\mathbf{R}_x(\vartheta)$.

In practice, to approximate the expectation operation in computing $\mathbf{R}_{y_z}(\vartheta)$ in (28), we propose to take an average over $\mathbf{y}_{p,z}(\vartheta)$ at different scanning periods $p$ for P1 or at $P$ sensors in group $z$ for P2, i.e., $\mathbf{R}_{y_z}(\vartheta) = \frac{1}{P} \sum_{p=0}^{P-1} \mathbf{y}_{p,z}(\vartheta)\mathbf{y}_{p,z}^H(\vartheta)$. Introducing $\tilde{\mathbf{r}}_{y_z}(\vartheta) = \mathbf{vec}(\mathbf{R}_{y_z}(\vartheta))$, the LS reconstruction is then applied to $\tilde{\mathbf{r}}_{y_z}(\vartheta) = [\mathbf{r}_{y_0}^T(\vartheta), \mathbf{r}_{y_1}^T(\vartheta), \ldots, \mathbf{r}_{y_{Z-1}}^T(\vartheta)]^T$.

VIII. NUMERICAL STUDY

A. Uncorrelated Bins

In this section, we simulate the estimation and detection performance of the CAP approach for the uncorrelated bins case discussed in Sections III-VII. To keep the study general, in this section, we generally simulate the multi-cluster scenario of Section VII. In our first experiment, we consider problem P2 and have $N = 3000$, $L = 170$, and $N = 18$. Each sensor collects $M = 5$ samples out of every $N = 18$ possible samples based on a periodic length-17 minimal circular sparse ruler with $M = \{0, 1, 4, 7, 9\}$. This is identical to forming a $5 \times 18$ matrix $\mathbf{C}$ in (11) by selecting the rows of $\mathbf{I}_{18}$ based on $\mathbf{M}$. The resulting $\mathbf{R}_c$ in (13) has full column rank and we have a compression rate of $M/N = 0.28$. We consider $K = 6$ user signals whose frequency bands are given in Table I together with the power at each band normalized by frequency. We generate these signals by passing six circular complex zero-mean Gaussian i.i.d. noise signals through different digital filters having 200 taps where the location of the unit-gain passband of the filter for each signal corresponds to the six different active bands. We set the variances of these noise signals based on the desired user signal powers in Table I. We assume $D = 2$ clusters of $\tau = 100$ unsynchronized sensors, which means that, at a given point in time, different sensors observe different parts of the user signals. To simplify the experiment, the correlation between the different parts of the user signals observed by different sensors is assumed to be negligible such that they can be viewed as independent realizations of the user signals. The spatially and temporally white noise has a variance of $\sigma^2 = 7$ dBm. The signal of each user received by different sensors is assumed to pass through different and uncorrelated fading channels $H_1^{(6)}(\vartheta)$. Note however that the signal from a user received by sensors within the same cluster is assumed to suffer from the same path loss and shadowing. The amount of path loss experienced between each user and each cluster listed in Table I includes the shadowing to simplify the simulation. We simulate small-scale Rayleigh fading on top of the path loss by generating the channel frequency response based on a zero-mean complex Gaussian distribution with variance given by the path loss in Table I. We assume flat fading in each band.

Fig. 4 shows the CAP of the faded user signals received at the sensors. As a benchmark, we provide the Nyquist-rate based AP (NAP), which is obtained when all sensors collect all the $N$ samples. With respect to the NAP, the degradation in the quality of the CAP is acceptable despite a strong compression, although more leakage is introduced in the unoccupied band. Next, we perform 1000 Monte Carlo runs and vary the number of sensors per cluster $\tau$, the noise variance at each sensor $\sigma^2$, and $M/N$ (see Fig. 5). In Fig. 5, the compression rate of $M/N = 0.44$ is implemented by activating three extra cosets, i.e., $\{2, 12, 14\}$ (which we picked randomly). Fig. 5 shows the normalized mean square error (NMSE) of the CAP with respect to the NAP and indicates that increasing $M/N$ by a factor of less than two significantly improves the estimation quality. Having more sensors $\tau$ also improves the estimation quality. Also observe that the compression introduces a larger NMSE for a larger noise power.

We can also re-interpret the first experiment for problem P1. In P1, the first experiment implies that $M = 5$ ULSs (whose indices are indicated by $\mathbf{M}$) out of $N = 18$ ULSs are activated leading to a periodic circular MRA. Table I then gives the angular bands of the $K = 6$ user signals and the power for each band normalized by the angle. For P1, the first experiment also implies that each user transmits temporally independent signals and that the signals from different users $k$ pass through statistically different and uncorrelated time-
TABLE II
THE FREQUENCY BAND AND THE POWER OF THE USERS SIGNAL AND THE EXPERIENCED PATH LOSS IN THE FIRST, SECOND, AND THIRD EXPERIMENTS.

| User band (rad/sample) | Power/freq. (per rad/sample) | Path loss at cluster 1 | Path loss at cluster 2 |
|------------------------|-----------------------------|------------------------|------------------------|
| 10 dBm                 | 10 dBm                      | 17 dB                  | 19 dB                  |
| -10 dBm                | -12 dB                      | 0 dB                   | -10 dB                 |
| 20 dBm                 | -16 dB                      | 0 dB                   | -10 dB                 |
| -20 dBm                | -14 dB                      | 0 dB                   | -10 dB                 |
| 30 dBm                 | -18 dB                      | 0 dB                   | -10 dB                 |
| -30 dBm                | -20 dB                      | 0 dB                   | -10 dB                 |

Fig. 4. The CAP and the NAP of the faded user signals for the first experiment (unsynchronized sensors) as a function of frequency in a linear scale (top) and logarithmic scale (bottom).

Fig. 5. The NMSE between the CAP and the NAP for the first experiment (unsynchronized sensors).

Fig. 6. The CAP and the NAP of the faded user signals for the second experiment (synchronized sensors) as a function of frequency in a linear scale (top) and logarithmic scale (bottom).

Fig. 7. The NMSE between the CAP and the NAP for the second experiment (synchronized sensors).

general, some trends found in the unsynchronized sensors case also appear here. Notice that the NMSE for the synchronized sensors case is smaller than the one for the unsynchronized sensors case since the quality of the NAP in the synchronized sensors case is also significantly worse than the one in the unsynchronized sensors case. Note that we can also re-interpret this second experiment for problem P1. This re-interpretation however, will make more sense, if we reverse the roles of \( H^k_t (\vartheta) \) and \( U^L_k (\vartheta) \). When this is the case, for P1, the second experiment implies that each user transmits temporally independent signals and that the signals from different users \( k \) pass through statistically different and uncorrelated time-invariant fading channels on their way towards the receiving array. Here, the statistics of the user signal are constant only within a cluster of time indices.

In the third experiment, we investigate the impact of varying the bin size (which is equivalent to varying \( N \)) and \( L \) for a given \( \tilde{N} \) on the performance of the CAP approach. Let us consider the settings in the first experiment (i.e., we consider Table III except for the following. We now examine three different values of \( N \), i.e., \( N = 10 \), \( N = 14 \), and \( N = 18 \) for a given \( \tilde{N} = 3150 \). For each value of \( N \), we vary the compression rate \( M/N \) and examine the two sets of coset patterns available in Table III. We start from the minimal \( M/N \) offered by the minimal circular sparse ruler. Larger
compression rates are implemented by selecting additional coset indices where the order of the selection is provided by the third column of Table III. We fix the number of $\tau$ to $\tau = 76$ and perform 1000 Monte Carlo simulation runs for different noise variances (see Fig. 8). Fig. 8 illustrates the NMSE of the CAP with respect to the NAP for the two sets of coset patterns. Observe that varying $N$ and $L$ for a given $N$ does not really result in a clear trend in the estimation performance. While the performance of the CAP for $N = 10$ is worse than the one for the larger value of $N$, the performance of the CAP for $N = 14$ is better than the one for $N = 18$ for some values of $M/N$. Note that the NMSE also depends on the coset pattern that we select to implement a particular compression. At this point, we would like to mention that, as long as the bin size constraint in Remark 2 is satisfied, having a larger $N$ is generally more advantageous as we will generally have a lower value of minimum $M/N$. This is because it can be found that, as $N$ increases, the number of marks in the corresponding length-$(N - 1)$ minimal circular sparse ruler (which is the minimum $M$) tends to be constant or to increase very slowly. As a result, the minimum compression rate $M/N$ also generally (even though not monotonically) decreases with $N$.

In the next three experiments, we use the CAP to detect the existence of active user signals that suffer from fading channels and evaluate the detection performance. We start with the fourth experiment, where we again consider problem P2, $\tilde{N} = 3060$, $L = 170$, $N = 18$, and $M/N = 0.28$ (again by adopting $\mathcal{M} = \{0, 1, 4, 7, 9\}$). We now consider $D = 3$ clusters of $\tau$ unsynchronized sensors and $K = 3$ user signals (see their settings in Table IV), which are generated using the same procedure used in the first experiment. The amount of path loss (which includes shadowing) experienced between each user and each cluster is listed in Table IV. We then simulate a small-scale Rayleigh fading channel on top of it. We perform 5000 Monte Carlo runs and vary $\tau$ and $\sigma^2$ (see Fig. 9). We vary the detection threshold manually and out of the $\tilde{N} = 3060$ frequency points at which the CAP is reconstructed, we evaluate the resulting detection events at 363 frequency points in the active bands and the false alarm events at 363 frequency points in the bands that are far from the active bands, i.e., $[-0.77\pi, -0.53\pi]$. Here, we average the estimated power over every eleven subsequent frequency points $\vartheta$ and apply the threshold to these average values. The resulting receiver operating characteristic (ROC) is depicted in Fig. 9. Observe the acceptable detection performance of the CAP for the examined $\tau$ and $\sigma^2$ though the performance is slightly poor for $\tau = 17$ and $\sigma^2 = 14$ dBm. This detection performance demonstrates that the proposed CAP can be used in a spectrum sensing application such as in a CR network.

TABLE III
THE TWO SETS OF COSET PATTERNS USED IN THE THIRD EXPERIMENT (COMPARISON OF DIFFERENT BIN SIZE).

| $N$ | Minimal circular sparse ruler indices | The order of the additional coset indices for implementing a larger compression rate |
|-----|--------------------------------------|--------------------------------------------------------------------------------|
| 18  | 0, 1, 4, 7, 9                         | 1, 2, 13, 12, 15, 6                                                            |
| 14  | 0, 1, 4, 7                            | 10, 6, 12, 5                                                                   |
| 10  | 0, 1, 3, 5                            | 8, 4                                                                           |

First set of coset patterns

| $N$ | Minimal circular sparse ruler indices | The order of the additional coset indices for implementing a larger compression rate |
|-----|--------------------------------------|--------------------------------------------------------------------------------|
| 18  | 0, 1, 4, 7, 9                         | 5, 2, 6, 17, 15, 14                                                            |
| 14  | 0, 1, 2, 4, 7                         | 12, 10, 13, 11                                                                |
| 10  | 0, 1, 3, 5                            | 4, 6                                                                           |

Second set of coset patterns

Fig. 8. The NMSE between the CAP and the NAP for the third experiment (comparison of different bin size); (a) using the first set of coset patterns (see Table III), (b) using the second set of coset patterns.

TABLE IV
THE FREQUENCY BAND AND THE POWER OF THE USER SIGNALS AND THE EXPERIENCED PATH LOSS IN THE FOURTH AND THE FIFTH EXPERIMENTS.

| User band (rad/sample) | Power/freq. (per rad/sample) | Path loss (in dB) at cluster |
|------------------------|-----------------------------|-----------------------------|
| $0.41\pi, 0.49\pi$     | 25 dBm                      | 1, 2, 3                      |
| $0.31\pi, 0.39\pi$     | 25 dBm                      | $-12$, $-14$, $-14$          |
| $0.21\pi, 0.29\pi$     | 25 dBm                      | $-13.5$, $-13$, $-12.5$      |

The fifth experiment repeats the fourth experiment but for synchronized sensors. The ROC in Fig. 10 shows that the detection performance for the synchronized sensors case is worse than the one for the unsynchronized sensors case in Fig. 9 due to the significant variation in the CAP as shown in Fig. 9.

In the sixth experiment, we consider problem P2 and compare the detection performance of the spectrum sensing approach based on CAP with that of the one based on the RM-FOCUSS discussed in Section V-E. To simulate the existence of a joint sparsity structure in $\{x(\theta)\}_{\theta=1}^\tau$, we again use the settings in Table IV. However, we now only assume one cluster of $\tau = 50$ sensors where the amount of path loss experienced between each user and each sensor is set to $-13$ dB. The ROC for 5000 Monte Carlo runs and different $M/N$ as well as $\sigma^2$ is illustrated in Fig. 11. Here, the compression rate of $M/N = 9/18$ is implemented by activating four extra cosets, i.e., $16, 8, 12, 13$ (which we decide randomly), on top of
parameter to 10 for the case of $M/N = 5/18$, to 0.01668 for the case of $M/N = 9/18$ and $\sigma^2 = 14$ dBm, and to 0.21544 for the case of $M/N = 9/18$ and $\sigma^2 = 11$ dBm (see Fig. 11). Observe from Fig. 11 that the spectrum sensing approach based on CAP has a better detection performance than the one based on signal/spectrum reconstruction using RM-FOCUSS. Recall that the approach of [24] requires the sparsity constraint on the vectors to be reconstructed (which are $\{|x_t(\theta)|\}_{\ell=1}^T$). This implies that, if we have additional active users on top of the scenario used in the sixth experiment, the actual $\{|x_t(\theta)|\}_{\ell=1}^T$ will have a smaller sparsity level. In this case, if we use the same compression rate $M/N$ as the one used in the sixth experiment, the performance of RM-FOCUSS will be even worse.

### B. Correlated Bins

In this section, we conduct the seventh experiment to evaluate the estimation performance of the CAP approach for the correlated bins case discussed in Section VII. Here, we consider problem P2, $N = 3080$, $L = 77$, $N = 40$, and $M = 14$ ($M/N = 0.35$). Recall from Section VII that the mathematical model for the correlated bins case is similar to the one in [19]. Hence, to design the sampling matrices for all sensors, which are assumed to be synchronized, that ensure the full column rank of $\Psi$ in (30), we use the algorithm of [19], which is originally designed to solve the antenna selection problem for estimating the DOA of highly correlated sources. This algorithm, which only offers a suboptimal solution for $Z$, suggests $Z = 12$ groups of $P = 25$ sensors where each group has a unique set of $M = 14$ active cosets. We consider $K = 2$ user signals whose setting is given in Table V. To simulate the full correlation between all the frequency components within the band of the $k$-th user, we assume that the $k$-th user transmits exactly the same symbol at all the frequency components of the one when the compressive signal reconstruction using RM-FOCUSS of [24] is used (the sixth experiment).
\begin{table}[h]
\centering
\caption{The frequency bands occupied by the users, their power, and the experienced path loss in the seventh experiment.}
\begin{tabular}{|c|c|c|}
\hline
User band (rad/sample) & Power/freq. (per rad/sample) & Path loss (dBm) \\
\hline
\(-0.8\pi, -0.2\pi\) & 22 dBm & -6 dB \\
\(0.1\pi, 0.9\pi\) & 25 dBm & -7 dB \\
\hline
\end{tabular}
\end{table}

Fig. 13. The NMSE between the CAP based on the correlated bins assumption and the NAP for the seventh experiment in Section VIII-B.

Fig. 14. The simulated and analytical NMSE between the CAP and the true power spectrum when \(x_t[\tilde{n}]\) only contains circular complex Gaussian i.i.d. noise. Unless mentioned otherwise, the cases of \(M/N > 0.28\) are implemented by activating extra cosets based on Pattern 1.

\begin{table}[h]
\centering
\caption{Three coset patterns to be added on top of the already selected minimal circular sparse ruler based coset indices for implementing \(M/N > 0.28\) in Section VIII-C.}
\begin{tabular}{|c|c|}
\hline
Coset pattern & The order of the additional coset indices \\
\hline
Pattern 1 & 17, 11, 2, 6 \\
Pattern 2 & 3, 5, 6, 8 \\
Pattern 3 & 2, 3, 5, 6 \\
\hline
\end{tabular}
\end{table}

C. Circular Complex Gaussian Noise

The last experiment examines the performance of the CAP based on the UB assumption when the received signal \(x_t[\tilde{n}]\) only contains circular complex zero-mean Gaussian spatially and temporally i.i.d. noise. Here, we have \(N = 3060\), \(L = 170\), \(N = 18\), and \(\sigma^2 = 7\) dBm. We perform 1000 Monte Carlo runs and vary \(\tau\) (see Fig. 14). We compute the NMSE of the CAP with respect to the true power spectrum (since \(x_t[\tilde{n}]\) in this case is clearly a WSS signal) and compare this NMSE obtained from the simulation with the analytical NMSE. Since it can be shown that, for circular complex Gaussian i.i.d. noise \(x_t[\tilde{n}]\), \(P_{x,LS}(\theta)\) is an unbiased estimate of \(P_x(\theta)\) even for finite \(N\), the analytical NMSE only depends on the variance of \(P_{x,LS}(\theta)\) and it can be shown to be equal to \(1/(\pi^2 + \sum_{n=1}^{N-1} 1/\gamma_n)\) by using (26). We start with \(M/N = 0.28\) by using the cosets indexed by the length-17 minimal circular sparse ruler, i.e., \(M = \{0, 1, 4, 7, 9\}\), and then vary \(M/N\). First, the cases of \(M/N > 0.28\) are implemented by activating additional cosets based on Pattern 1 in Table VI. Then, we also test Pattern 2 and Pattern 3 as additional coset patterns to implement the case of \(M/N = 0.5\).

Observe in Fig. 14 how the analytical NMSE is on top of the simulated NMSE for all the evaluated \(M/N\) values. Also observe that, for \(M/N = 0.5\), the three different coset patterns have led to different values of the NMSE depending on the resulting value of \(\{\gamma_{n+1}\}_{n=1}^{N-1}\) in (26).
IX. CONCLUSION AND FUTURE WORK

This paper proposed a compressive periodogram reconstruction approach and considered both time-frequency and spatio-angular domains. In our model, the entire band is split into uniform bins such that the received spectra at two frequencies or angles, whose distance is equal to or larger than the size of a bin, are uncorrelated. In both considered domains, this model leads to a circulant coset correlation matrix, which allows us to perform a strong compression yet to present our reconstruction problem as an overdetermined system. When the coset patterns are designed based on a circular sparse rule, the system matrix has full column rank and we can reconstruct the periodogram using LS. In a practical situation, our estimate of the coset correlation matrix is only asymptotically &cyclic;&cyclic;uant. Hence, we also presented an asymptotic bias and variance analysis for the CAP. We further included a thorough variance analysis on the case when the received signal only contains circular complex zero-mean white Gaussian noise, which provides some useful insights in the performance of our approach. The variance analysis for a more general signal (i.e., a general Gaussian signal) has also been presented but it is not easy to interpret due to its dependence on the unknown statistics of the user signals. We also proposed a solution for the case when the bin size is decreased such that the received spectra at two frequencies or angles, with a spacing between them larger than the size of the bin, can still be correlated. Finally, the simulation study showed that the estimation performance of the evaluated approach is acceptable and that our CAP performs well when detecting the existence of the user signals suffering from fading channels.

As a future work, we are interested in the case when both problems P1 and P2 emerge simultaneously. In that case, we would consider a compressive linear array of antennas and a compressive digital receiver unit per antenna leading to a two-dimensional (2D) digital signal. Our interest would then be to investigate if it is possible to perform compression in both the time and spatial domain and to jointly reconstruct the angular and frequency periodogram from the 2D compressive samples. To study that, we could follow an approach similar to [23], which assumes stationarity in both the time and spatial domain and exploits the existing Toeplitz structure in the correlation matrix.

APPENDIX A

PROOF OF THEOREM 2

Recall that $\hat{R}_\vartheta(\hat{\vartheta})$ in (15) is an unbiased estimate of $R_\vartheta(\vartheta)$ in (12), i.e., $E[\hat{R}_\vartheta(\hat{\vartheta})] = R_\vartheta(\vartheta)$. Applying the expectation operator on $\hat{P}_{x,LS}(\vartheta + \frac{i}{N})$ in (16) and $\hat{R}_{x,LS}(\vartheta)$ in (17), it is then clear that $\hat{P}_{x,LS}(\vartheta)$ in (16) and $\hat{R}_{x,LS}(\vartheta)$ in (17) are unbiased estimates of $R_x(\vartheta)$ in (13) and $R_x(\vartheta)$ in (17), respectively, since $\hat{R}_x(\vartheta)$ in (13) can perfectly be reconstructed from $\hat{R}_x(\vartheta)$ using LS. Recall from Remark 1 that the $(i+1)$-th diagonal element of $R_x(\vartheta)$ is equal to $E[|X_{t,i}(\vartheta)|^2]$. From (18), it is then obvious that the CAP $\hat{P}_{x,LS}(\vartheta + \frac{i}{N})$ is an unbiased estimate of $\frac{1}{N}E[|X_{t,i}(\vartheta)|^2]$. However, by taking (1) into account, we can observe that

$$\lim_{N \to \infty} \frac{1}{N}E[|X_{t,i}(\vartheta)|^2] = P_x(\vartheta + \frac{i}{N}), \ \vartheta \in [0,1/N], \quad (31)$$

for $i = 0,1,\ldots,N-1$, since $x_t[n]$ is a finite-length observation of the actual random process $x[n]$. Hence, by applying \(\lim_{N \to \infty} E[\hat{P}_{x,LS}(\vartheta + \frac{i}{N})] \) and using (31), it is clear that $\hat{P}_{x,LS}(\vartheta + \frac{i}{N})$ is an asymptotically (with respect to $N$) unbiased estimate of $P_x(\vartheta + \frac{i}{N})$ in (1), for $\vartheta \in [0,1/N)$ and $i = 0,1,\ldots,N-1$. □

APPENDIX B

PROOF OF PROPOSITION 1

Note that for the specific case assumed in this proposition, we can rewrite (20) as

$$\text{Cov}[[\hat{R}_\vartheta(\vartheta)]_{m+1,m'+1},[\hat{R}_\vartheta(\vartheta)]_{a+1,a'+1}] = \frac{1}{N^4\tau^2} \sum_{t=1}^{N-1,1} \sum_{i=0}^{N-1,1} \sum_{i'=0}^{N-1,1} \sum_{b'=0}^{N-1,1} \sum_{b=0}^{N-1,1} e^{j2\pi(n_m+n_n+n_b+n_{b'})(t-t') N} \times$$

$$E[X_{t,i}(\vartheta)X_{t',i'}(\vartheta)]E[X_{t',i'}(\vartheta)X_{t,b}(\vartheta)], \quad (32)$$

where we also take the circularity of $x_t[n]$ into account. By using $N = LN$, we can find that $E[X_{t,i}(\vartheta)X_{t,b}(\vartheta)] = \sigma^2 \sum_{b=0}^{N-1} e^{j2\pi n b N} = N \sigma^2 \delta[b-i]$, as it is clear from (32) that $b \in \{0,1,\ldots,N-1\}$. Hence, we can simplify (32) as

$$\text{Cov}[[\hat{R}_\vartheta(\vartheta)]_{m+1,m'+1},[\hat{R}_\vartheta(\vartheta)]_{a+1,a'+1}] = \tau \sum_{t=1}^{N-1,1} \sum_{i=0}^{N-1,1} \sum_{i'=0}^{N-1,1} \sum_{b=0}^{N-1,1} \sum_{b'=0}^{N-1,1} e^{j2\pi(n_m+n_n+n_b+n_{b'})(t-t') N} \times$$

$$\frac{L^2 \sigma^4}{N^2 \tau^2} \delta[b-i] \delta[\vartheta]\delta[\vartheta'], \quad (33)$$

where the last equality is due to $n_m \in \{0,1,\ldots,N-1\}$, for all $m$, and the fact that $n_m = n_a$ implies $m = a$. □

APPENDIX C

PROOF OF (23)

First, by recalling that $R_c = (C \otimes C) T$, we can write

$$\gamma_n = [R_c^T R_c]_{n,n} = [T^T ((C^T C) \otimes (C^T C)) T]_{n,n} = [T^T (\text{diag}(w) \otimes \text{diag}(w)) T]_{n,n} = \sum_{n=0}^{N-1} \sum_{n'=0}^{N-1} [T^T]_{n,n'+1} \times$$

$$\text{diag}(w) \otimes \text{diag}(w)]_{N+n+n'+1} \times \text{diag}(w) \otimes \text{diag}(w)]_{N+n+n'+1} \times \{T_{N+n+n'+1} \} \times (33)$$

Let us then recall that the $(q+1)$-th row of $T$ is given by the $(q - \frac{1}{2}) \mod N + 1$-th row of $I_N$. We can then find that the $(i+1)$-th row of $T^T$ contains ones at the $\{N+n+(i+1) \mod N + 1\}_{n=0}^{N-1}$-th entries and zeros elsewhere. We can thus rewrite (33)

$$\gamma_n = \sum_{n=0}^{N-1} \{w \otimes \text{diag}(w) \} \times$$

$$\text{diag}(w) \otimes \text{diag}(w)]_{N+n+(n+1) \mod N + 1} \times (33)$$

$$= \sum_{n=0}^{N-1} \{w \otimes \text{diag}(w) \} \times$$

$$\text{diag}(w) \otimes \text{diag}(w)]_{(n+1) \mod N + 1} \times (33)$$
where we use $w w^T = \text{vec}^{-1}(w \otimes w)$ in the second equation with $\text{vec}^{-1}(\cdot)$ the inverse of the vec$(\cdot)$ operation.

\section*{Appendix D
Proof of Theorem 3}

To simplify the discussion, we introduce the $N \times 1$ vector

$$\hat{\rho}_x(\vartheta) = (C \otimes C)^T \text{vec}(R_g(\vartheta)).$$

(35)

From the definition of $C$ in Section II-A, it is clear that the $(Nf + g + 1)$-th row of $(C \otimes C)^T$ contains a single one at a certain entry and zeros elsewhere only if $f, g \in \mathcal{M}$, otherwise it contains zeros at all entries. Hence, we can write

$$[\hat{\rho}_x(\vartheta)]_{Nf+g+1} = 0, \quad \text{if } f \not\in \mathcal{M} \text{ or } g \not\in \mathcal{M}. \quad (36)$$

When $f, g \in \mathcal{M}$, the $(Nf + g + 1)$-th entry of $\hat{\rho}_x(\vartheta)$ is given by one of the entries of vec$(R_g(\vartheta))$. Recall from Appendix E that the $(i+1)$-th row of $T^\ell$ contains one at the set $\{Nn + (n+i)\}$ and zeros elsewhere. As a result, we can use (36), (35), and Remark 3 to write the $(i+1)$-th entry of $\hat{R}_{x,LS}(\vartheta)$ in (16) as

$$[\hat{R}_{x,LS}(\vartheta)]_{i+1} = \frac{1}{\gamma_i + 1} [T^\ell \hat{\rho}_x(\vartheta)]_{i+1}$$

(37)

with $\ell = 0, 1, \ldots, N-1$ and vec$^{-1}(\hat{\rho}_x(\vartheta))$ an $N \times N$ matrix.

At this stage, let us introduce the following definition.

\textbf{Definition 3: Define the collection of }$\text{vec}^{-1}(\hat{\rho}_x(\vartheta))$\textbf{ at }$f, g \in \{0, 1, \ldots, N-1\}$\textbf{ and all }$(g' - f')$\textbf{ mod }$N + 1 = \kappa$\textbf{ as the }$\kappa$\textbf{-th modular diagonal of }$\text{vec}^{-1}(\hat{\rho}_x(\vartheta))$. \textbf{Note that the first modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$ is its main diagonal.}

We use Definition 3 to formulate the following lemma.

\textbf{Lemma 1:} The $\kappa$-th modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$ in (37) contain only $\gamma_\kappa$ entries of vec$(R_g(\vartheta))$ in (35). The remaining $N - \gamma_\kappa$ entries of the $\kappa$-th modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$ are equal to zeros. The summation in (37) then involves $N - \gamma_\kappa + 1$ zeros and only $\gamma_\kappa + 1$ out of $M^2$ entries of vec$(R_g(\vartheta))$.

\textbf{Proof:} Recall that, when $f, g \in \mathcal{M}$, the $(Nf + g + 1)$-th entry of $\hat{\rho}_x(\vartheta)$ in (37) is given by one of the entries of vec$(R_g(\vartheta))$. Since Remark 3 indicates that the number of pairs $g, f \in \mathcal{M}$ that lead to $(g - f) \text{ mod } N + 1 = \kappa$ is equal to $\gamma_\kappa$, it is clear from Definition 3 that the $\kappa$-th modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$ only contains $\gamma_\kappa$ entries of vec$(R_g(\vartheta))$.

Equation (35) then confirms that the remaining $N - \gamma_\kappa$ entries of the $\kappa$-th modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$ are equal to zero. Next, observe that the summation in (37) is the sum of all terms in the $(i+1)$-th modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$. This can be found by applying Definition 3 on the column and row indices of vec$^{-1}(\hat{\rho}_x(\vartheta))$ in (37), i.e.,

$$(n+i) \text{ mod } N - n \text{ mod } N + 1 = (n + \nu - n) \text{ mod } N + 1 = \nu + 1,$$

which exploits the property that $(\kappa \mod N + \kappa') \mod N = (\kappa + \kappa') \mod N$. This concludes the proof. \hfill \Box

Let us now define $\Sigma_{\hat{x}}(\vartheta)$ as the $N^2 \times N^2$ covariance matrix of $\hat{\rho}_x(\vartheta)$ in (35), which can be written as $\Sigma_{\hat{x}}(\vartheta) = (C \otimes C)^T \Sigma_{R_g}(\vartheta)(C \otimes C)$. First, recall (35) and that when $f, g \in \mathcal{M}$, the $(Nf + g + 1)$-th entry of $\hat{\rho}_x(\vartheta)$ in (37) is given by one of the entries of vec$(R_g(\vartheta))$. By also recalling that, for circular complex Gaussian i.i.d. noise $x_{\nu}[\hat{\nu}]$, $\Sigma_{R_g}(\vartheta)$ is a diagonal matrix whose elements are given by (24), we can find that $\Sigma_{\hat{x}}(\vartheta)$ is also a diagonal matrix with its diagonal elements given by

$$\text{diag}(\Sigma_{\hat{x}}(\vartheta))_{Nf+g+1} = \left\{ \begin{array}{ll} \frac{L^2}{2\pi} & \text{if } f, g \in \mathcal{M}, \\
0 & \text{if } f \not\in \mathcal{M} \text{ or } g \not\in \mathcal{M}. \end{array} \right. \quad (38)$$

By taking (37), (38), and the diagonal structure of $\Sigma_{\hat{x}}(\vartheta)$ into account, we can then write the entry of $\Sigma_{R_{x,LS}}(\vartheta)$ in (21) at the $(i+1)$-th row and the $(\nu + 1)$-th column as

$$\text{Cov}([\hat{R}_{x,LS}(\vartheta)]_{i+1}, [\hat{R}_{x,LS}(\vartheta)]_{\nu+1}) = \frac{1}{\gamma_{\nu+1}} \times$$

$$\sum_{n=0}^{N-1} \sum_{n'=0}^{N-1} \left\{ [T^\nu]_{Nn+n'+1,Nn+n'+1} \right\} \left\{ [T]_{Nn+n'+1,\nu+1} \right\} = \frac{\delta_{\nu+1}}{\gamma_{\nu+1}} \times$$

$$\sum_{n=0}^{N-1} \sum_{n'=0}^{N-1} \left\{ \Sigma_{R_g}([\hat{\rho}_x(\vartheta)]_{Nn+n'+1}) \right\} \times \left\{ \Sigma_{R_g}(\nu+1) \right\}, \quad (39)$$

for $\nu, \nu' = 0, 1, \ldots, N-1$, which implies that $\Sigma_{R_{x,LS}}(\vartheta)$ is also a diagonal matrix for circular complex Gaussian i.i.d. noise $x_{\nu}[\hat{\nu}]$. Recall from the proof of Lemma 1 that the summation in (37) is the sum of all terms in the $(i+1)$-th modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$. We can then observe that the summation in (39) is the sum of the variance of each term in the $(i+1)$-th modular diagonal of vec$^{-1}(\hat{\rho}_x(\vartheta))$. Using Lemma 1 and (38), we can rewrite (40) as

$$\text{Cov}([\hat{R}_{x,LS}(\vartheta)]_{i+1}, [\hat{R}_{x,LS}(\vartheta)]_{\nu+1}) = \frac{L^2 \sigma^4}{\gamma_{\nu+1}} \delta_{\nu+1}, \quad (40)$$

for $\nu, \nu' = 0, 1, \ldots, N-1$. By considering (22) and noticing that $[B^T \otimes B^H]\{N_{i+1}, N_{n'+1}\} = \frac{1}{N^2} e^{-\frac{2\pi}{N} (n' - m)}$, let us rewrite $\text{Var}(\hat{P}_{x,LS}(\vartheta + i))$ in (23), for $\vartheta \in [0, 1/N)$ and $i = 0, 1, \ldots, N-1$, as

$$\text{Var}(\hat{P}_{x,LS}(\vartheta + i)) = \frac{N^4}{N^2} \sum_{n=0}^{N-1} \sum_{n'=0}^{N-1} \sum_{\nu=0}^{N-1} \sum_{\nu'=0}^{N-1}$$

$$\left\{ [B^T \otimes B^H]\{N_{i+1}, N_{n'+1}\} \times [T]_{Nn+n'+1,\nu+1} \right\} \left\{ [T]_{Nn+n'+1,\nu+1} \right\}, \quad (41)$$

We now recall that the $(g + 1)$-th row of $T$ is given by the set $\{g - \left\lfloor \frac{\kappa}{N} \right\rfloor \mod N + 1\}$-th row of $I_N$, exploit the diagonal structure of $\Sigma_{R_{x,LS}}(\vartheta)$ for circular complex Gaussian i.i.d. noise $x_{\nu}[\hat{\nu}]$, and use (40) to write

$$\text{Var}(\hat{P}_{x,LS}(\vartheta + i)) = \frac{N^2}{N^2} \sum_{n=0}^{N-1} \sum_{n'=0}^{N-1} \sum_{\nu=0}^{N-1} \sum_{\nu'=0}^{N-1} [\Sigma_{R_{x,LS}}(\vartheta)]_{Nn+n'+1,\nu+1}$$

$$[\Sigma_{R_{x,LS}}(\vartheta)]_{Nn+n'+1,\nu+1}$$

$$\times [\Sigma_{R_{x,LS}}(\vartheta)]_{Nn+n'+1,\nu+1}.$$
\[
\frac{L^2 \sigma^4}{\gamma} \sum_{n=0}^{N-1} \frac{1}{\gamma_{n+1}} \left[ T \right]_{Nn+n'+1, \tau+1} \left[ T^T \right]_{\tau+1, Nn'+1} \delta \left( (n' - n) \mod N - (\nu' - \nu) \mod N \right),
\]

(42)

for \( n, n', \nu, \nu' = 0, 1, \ldots, N - 1 \). By inserting (42) into (41), the variance of \( P_x,LS (\theta + \frac{i}{N}) \), for circular complex Gaussian i.i.d. noise \( x_t[i] \) and \( i = 0, 1, \ldots, N - 1 \), is given by

\[
\text{Var} \left[ P_x,LS \left( \theta + \frac{i}{N} \right) \right] = \frac{1}{L^2 N^2} \sum_{n=0}^{N-1} \sum_{n'=0}^{N-1} \tau \gamma \left( (n' - n) \mod N + 1 \right)
\]

\[
= \frac{\sigma^4}{\tau} \sum_{n=0}^{N-1} \frac{1}{\gamma_{n+1}} = \frac{\sigma^4}{M \tau} + \frac{\sigma^4}{\tau} \sum_{n=1}^{N-1} \frac{1}{\gamma_{n+1}}, \quad \theta \in [0, 1/N),
\]

where we use the last part of Remark 3 in the last equality. □
