Abstract—Event-related desynchronization and synchronization (ERD/S) and movement-related cortical potentials (MRCP) play an important role in brain-computer interfaces (BCI) for lower limb rehabilitation, particularly in standing and sitting. However, little is known about the differences in the cortical activation between standing and sitting, especially how the brain’s intention modulates the pre-movement sensorimotor rhythm as they do for switching movements. In this study, we aim to investigate the decoding of continuous EEG rhythms during action observation (AO), motor imagery (MI), and motor execution (ME) for standing and sitting. We developed a behavioral task in which participants were instructed to perform both AO and MI/ME in regard to the actions of sit-to-stand and stand-to-sit. Our results demonstrated that the ERD was prominent during AO, whereas ERS was typical during MI at the alpha band across the sensorimotor area. A combination of the filter bank common spatial pattern (FBCSP) and support vector machine (SVM) for classification was used for both offline and pseudo-online analysis. The offline analysis indicated the classification of AO and MI providing the highest mean accuracy at 82.73±2.38% in stand-to-sit transition. The results were acceptable in comparison to the original FBCSP study of right hand and right foot activation classifications. By applying the pseudo-online analysis, we demonstrated the possibility of decoding neural intentions from the integration of both AO and MI. These observations led us to the promising aspect of using our developed tasks to build future exoskeleton-based rehabilitation systems.

Index Terms—Brain-computer interfaces, motor imagery, event-related desynchronization and synchronization, movement-related cortical potentials, action observation.

I. INTRODUCTION

The use of brain-computer interface (BCI) technology as a rehabilitation approach for motor disorders has become more extensive within the recent years. Within the past decade, there have been uses of BCI in a therapeutic setting, such as the use of motor imagery (MI) and virtual reality (VR) in post-stroke therapy [1]–[3]. The effectiveness of BCI technology in clinical settings has spanned to the development of exoskeleton for the rehabilitation of patients with multiple motor and motor-related disorders, such as upper limb exoskeleton [4]–[6]. Indeed, BCI technology has been found to be an effective rehabilitation approach to motor related complications as a result of stroke, for example, with an increase in the upper limb strength as measured by the Fugl-Meyer Motor Assessment (FMMA) after the implementation of MI based BCI [7], [8]. In order for the BCI technology to be effective, it is essential that the users are able to control the exoskeleton system via methods such as biofeedback from electroencephalography (EEG), electromyography (EMG), and electrooculography (EOG) [9].

Event-related desynchronisation/synchronisation (ERD/S) are cortical rhythms characterized by the mu (8–13 Hz) and beta (14–30 Hz) neural activity patterns [10], [11]. As ERD/S are prominent during MI of limb movements, ERD/S based BCI has shown potentials for the rehabilitation of motor disorders [11], [12]. Supporting this notion of ERD in motor preparation and inhibition is the study on experimental participants in a unilateral wrist extension task based on visual cues, in which mu ERD showed stronger contra-lateralization features with movement intention and execution in the sensorimotor cortices [13], [14] whereas ERS was found prominently in the ipsilateral hemisphere [15]. In order to implement ERD/S based BCI in exoskeleton, EMG is often used to modulate the gait pattern of the exoskeleton, whilst algorithms such as common spatial patterns (CSP) has been used to decode the MI task done by a participant [16]. However, another factor that must be taken into account is the motor planning, which involves the intention of a person prior to the execution of a movement. One way in which the rehabilitation via BCI can be achieved is by altering the neural activities of a person using methods such as modulating pre-movement sensorimotor
rhythm (SMR) [17]. In rehabilitative settings, SMR can be altered via instructions, a process known as learned modulation [18]. There is evidence supporting the effectiveness of learned modulation on motor performance after training with EEG based feedback [19], [20]. Specifically, the decrease in the amplitude of pre-movement SMR correlated with a more accurate performance in a target matching task, implicating that ERD will support motor functions due to the correlation between ERD and motor accuracy [17].

Movement-related cortical potentials (MRCPs) are spontaneous potentials that are generated during a person-generated planning and motor execution (ME), which can be an actual movement or imaginary [21], [22]. MRCP generally consists of two main parts called a Bereitschaftspotential (BP), or readiness potential (RP), and a movement-monitoring potential (MMP) [23], [24]. In addition to ERD/S, MRCP can be used to decode motor intention and planning [21]. One aim of the current study is to evaluate the competencies of ERD/S and MRCP in terms of their reflections of movement intentions, specifically regarding the contributions of the current research design on future research in rehabilitative exoskeleton systems. In healthy participants, there are no effects of subject training on MRCP based BCI technology [25]. In motor rehabilitation, MRCP is thought to underlie neuroplasticity, which can be implemented faster when using BCI systems with high signal-to-noise ratio and lowered calibration time [26], [27].

Nevertheless, only a small amount of studies has been conducted on how the brain mediates different complex gait movements such as running and walking [28]. As there is less work on the complexity of shifting from sitting to standing and vice versa, the current study aimed to combine action observation (AO) and MI as a potential rehabilitation strategy for lower limbs dysfunction. To assess the roles of AO, continuous EEG rhythms were collected throughout the entire experimental procedure, which included AO, MI, and resting (R) states. Participants were instructed to perform both actions of AO and MI in regard to standing and sitting, which were alternated between the actions of sit-to-stand and stand-to-sit. Due to the increase in the alpha and beta patterns as a result of “push-off” (heel striking) actions, we expected to see the differences in the cortical activation between standing and sitting in the sense that the act of transitioning from sitting to standing would result in the act of push-off [29].

There are two major contributions of the current study:

1) To our best knowledge, the current study is the first to explore lower limb motor functions using action observation (AO), motor imagery (MI), and motor execution (ME) together before distinguishing between individual EEG correlates, with each state showing different cortical activation patterns. Specifically, we looked at the EEG potentials during resting, sit-to-stand and stand-to-sit. During each trial, a video of a person performing the actions was shown. The design is expected to facilitate the future exoskeleton-based rehabilitation that integrates both AO and MI. This is further discussed in Discussion A.

2) Using the state-of-the-art machine learning algorithms and pseudo-online scheme, our classification approaches are shown to distinguish between the resting (R) versus AO and AO versus task performance (MI or ME). Although multivariate pattern analysis (MVPA) was proposed as an analysis method for multiple brain activations across participants, the order of participants entered was found to be sensitive [30]. With pseudo-online scheme and two classifications, we enabled the practical assessment of classifier performance in this study. Further discussion regarding the algorithms and EEG classifications can be found in Discussion C.

From our findings, we aimed to contribute to a smoother interface between user and the exoskeleton system, which is the main challenge of implementing rehabilitative exoskeleton technology [31].

II. METHODS

A. Participants

The recruited participants comprised 8 healthy individuals (3 males, 5 females; 20–29 years old) with no history of neurological disorder, lower limb pathology, or gait abnormalities. All participants gave their informed consent prior to the experimental procedure following the Helsinki Declaration of 1975 (as revised in 2000). The study was approved by Rayong Hospital Research Ethics Committee (RYH REC No.E015/2562), Thailand.

B. Experimental Protocol

To investigate the feasibility of decoding the MI and MRCP signals during the intended movement executions with continuous EEG recordings, the entire experimental procedure composed of two sessions: MI and ME. Each session consisted of 3 runs (5 trials each), incorporating a total of 30 trials. The protocol began with a sitting posture, followed by 5 repeated trials of sit-to-stand and stand-to-sit tasks alternatively. Figure 1 displays the sequence of four states in each trial: R, AO, idle, and task performing states (MI or ME). During the R state, a black screen was displayed on the monitor for 5 seconds (s). The participants were instructed to remain relaxed and motionless. To avoid the ambiguity of the instructions, a video stimulus showing the sit-to-stand or stand-to-sit video task lasted for 4 to 5 s was presented to guide the participants in the AO state. The participants were instructed to perform the given task following an audio cue (beep) within 4 s. In the ME, the participants were to complete a succession of self-paced voluntary movement executions. Whereas in the MI, the participants were to commence motion imagining immediately after the audio cue.
C. Data Acquisition

Continuous EEG, EOG, and EMG signals were recorded simultaneously throughout the experiment. A biosignal amplifier (g.USBamp RESEARCH, g.tec, Austria) was used to acquire EEG and EOG signals. The EEG signals were obtained using 11 electrodes, positioned according to the 10-20 international system at the following placements: FCz, C3, Cz, C4, CP3, CPz, CP4, P3, Pz, P4, and POz, with the reference and the ground electrodes placed on the earlobes. EOG signals were acquired from 2 electrodes positioned under and next to the outer canthus of the right eye. The impedance of both EEG and EOG signals was maintained at below 10 kΩ throughout the experiment and the sampling rate was set to 1200 Hz. An OpenBCI was used to record EMG signals to identify the onset of the movement. 6 electrodes were placed on rectus femoris (RF), tibialis anticus (TA), and gastrocnemius lateralis (GL) of two lower limbs with 250 Hz sampling rate.

D. EEG Pre-processing

The offline signal processing was performed using MNE-python package (version 0.20.0) [32]. The pre-processing process was divided into two main steps: EEG-based MI and EEG-based MRCP during both MI and ME. Figure 2 illustrates the course of EEG, EOG, and EMG data processing.

Motor Imagery: The notch filter was set at 50 Hz to reduce the electrical noises. The recorded EEG and EOG signals were band-pass filtered between 1–40 Hz, using 2nd order non-causal Butterworth filter. Both signals were down-sampled to 250 Hz. An eye movement-related artifact correction based on independence component analysis (ICA) [33], [34] was applied to the EOG signals for the identification of artifact components which were removed from the EEG data. The EEG signals were segmented in epochs locked to the onset of each class (R, AO, and MI) for 4 s, as shown in Figure 1 followed by the pre-processing using a 2 s sliding window with a 0.2 s shift. The processed data for each class from each participant contained a collection of trials \( \times \) channels \( \times \) time points \((15 \times 11 \times 500)\).

Movement-related Cortical Potentials: A threshold-based method generally plays a significant role in extracting the actual movement onset detected by the EMG [35], [36]. In this study, we employed the threshold-based method to determine the actual movement onset of each sit-to-stand/stand-to-sit transition. The Teager-Kaiser energy operator (TKEO) [37] was firstly applied to each EMG channel to enhance the signal-to-noise ratio for the onset detection. The signals were then rectified using the absolute value and low-pass filtered at 3 Hz (2nd order non-causal Butterworth filter) to compute the linear envelope. A time window of 2 s before the audio cue was selected as the reference signal as no explicit movement should be occurred in this time interval. The linear envelope of the signals was applied to calculate the threshold \((T)\), which was set as \(T = \mu + h \times \sigma\), where \(\mu\) and \(\sigma\) were the mean and standard deviation (SD) of the reference signal. Moreover, \(h\) was varied from 3 to 20 where the highest classification accuracy was selected from. \(h = 10\) was used for the calculation of \(T\). Owing to the concerned related to the fallibility of identifying the movement onset, the onset was determined by considering the number of consecutive samples \((E)\) where the EMG envelopes exceeded the \(T\). We empirically defined \(E\) as 5. Therefore, the first time point was marked as the actual movement onset, when more than \(E\) (5) consecutive samples exceeded the \(T\).

The MRCP signals were extracted from the selected EEG signals recorded during the ME. The EEG signals were then high-pass filtered at 0.05 Hz (2nd order non-causal Butterworth filter). The notch filter frequency rate was defined at 50 Hz to filter out the electrical noises. Next, the EEG signals were down-sampled from 1200 to 250 Hz. The eye movement-related artifacts were removed, using the same ICA as the EEG-MI pre-processing protocol. The time-locked EEG and EMG signals were segmented into pre-movement and resting periods, based on the actual movement onset from the EMG signals. Each pre-movement epoch comprised the EEG signals from -1.5 to 1 s, which were identified as the “MRCPs” class. Each resting epoch consisted of the EEG signals in AO state from 4 to 6.5 s, defined as the “AO” class. After the MRCPs extraction was completed, the data from each class were converted into a sequence of sub-samples or sliding windows with a 1 s sliding window and a step of 0.5 s. The processed MRCPs and AO data from each participant were formed in a dimension of trials \( \times \) channels \( \times \) time points \((15 \times 11 \times 625)\).
E. Qualitative Analysis

Time-frequency analysis was utilized using EEGLAB toolbox (version 2019.0) [43] to visualize sit-to-stand and stand-to-sit executions during the MI session after performing ICA method in the aforementioned pre-processing. Event-Related Spectral Perturbations (ERSP) method [39] was performed using the Morlet wavelets transform to compute the power spectra. The baseline reference was then taken from -1 to 0 s at the beginning of the R state. The average of the spectral power changes was calculated at each time while normalized by the baseline spectra at the frequency ranges from 4 to 40 Hz. The significance of deviations from the baseline was analyzed using bootstrap method ($p = 0.05$).

To exhibit the qualitative result of MRCP signals, all of the 2.5 s from the extracted MRCP signals (15 trials executed by each participant) before formulating the sliding windows were considered, as shown in Figure 1 (b). The signals were then re-referenced using current source density (CSD) with spherical spline interpolations to enhance the unsatisfactory spatial resolution of EEG data [40]–[42]. The CSD were applied to the extracted MRCPs from all 11 EEG channels to remove the overall background activity. Subsequently, the grand average MRCP waveform was generated for each sit-to-stand/stand-to-sit transition using the average value of every trial across the 8 participants.

F. Offline Analysis

To demonstrate the possibility of decoding the MI and MRCP signals, the binary classification tasks on both signals were designed based on the exoskeleton system with the ability to identify and control each exact movement (standing or sitting). Thus, each sit-to-stand/stand-to-sit transition was conducted using the classification tasks separately. In the MI session, two classification tasks (R versus AO and AO versus MI) for neural decoding of the standing and sitting movements were conducted. In the ME session, one classification task (AO versus MRCPs) was performed, owing to the absence of both R and AO signals in the lower delta band (0.1–3 Hz).

Subject independent classification tasks were implemented with leave-one-(trial)-out cross-validation (LOOCV) on 15 trials (15 folds) using Scikit-learn [43], as exhibited in Figure 3. Each fold composed of 14 trials as the training set and the remaining trial as the testing set. During the training session, signal pre-processing was firstly performed on the training set, as depicted in Figure 2. The spatial features were then extracted from the processed training set using the filter bank common spatial pattern (FBCSP), producing the feature vectors for the classification task. Importantly, the FBCSP performs generally well in MI classification tasks [44]–[46]. The FBCSP was introduced as an extension of the common spatial pattern (CSP) to autonomously select the discriminated EEG features from multiple filter banks. In this study, 9 filter bank band-pass filters with a bandwidth of 4 Hz from 4 to 40 Hz (4–8 Hz, 8–12 Hz, ..., 36–40 Hz) were created for the MI. 6 filter bank band-pass filters were built with a bandwidth of 0.4 Hz for the 1st band and a bandwidth of 0.5 Hz for the other bands from 0.1–3 Hz (0.1–0.5 Hz, 0.5–1 Hz, ..., 2.5–3 Hz) for the ME.

Subsequently, a hyperparameter optimization algorithm, named grid search [47], was applied to the tuning of the optimal set of hyperparameters in the classification model, named support vector machine (SVM) [48]. For the SVM-based classification, the hyperparameters included kernel (linear, rbf, sigmoid), C (0.001, 0.01, 0.1, 1, 10, 25, 50, 100, 1000), and gamma (“auto”, 0.01, 0.001, 0.0001, 0.00001). By considering the grid search algorithm, the classification was implemented with a 10-fold stratified cross-validation. Finally, the prediction on the testing set of the classification model in each fold with optimal hyperparameters was evaluated. To compare the binary classification results within each MI/ME task for sit-to-stand and stand-to-sit transitions, a paired t-test with the unequal variances was used to determine the difference in the classification accuracy.

G. Pseudo-online analysis

Similar to the offline analysis, pseudo-online analysis was performed using the LOOCV scheme with the same training
models and the grid search algorithm. In the MI session, the period of data evaluation was modified from 0–13 s, whilst the duration was from 4–13 s in the ME session. Each epoch was likewise pre-processed with the same protocol as in the offline analysis to construct the continuous pseudo-online classification. However, the data were streamed in segregated segments, each with a 2 s sliding window with a 0.2 s shift. In order to investigate the feasibility of decoding the 3 classes of two steps-binary classification models in the MI session (R versus AO and AO versus MI) for the sit-to-stand/stand-to-sit transition, R versus AO classification model was used to evaluate the data in the first step. As shown in Figure 4, when the AO was produced after 5 consecutive detections (AO ≥ 5), the most optimal value was empirically selected among various participants. The algorithm was fashioned to determine which binary classification model was suitable. In the ME session, however, only AO versus MRCP model was decoded, where data were streamed in 1 s segment with a 0.5 s shift.

The performance of pseudo-online analysis was calculated using 3 parameters:

True positive rate (TPR) indicates the percentage of MI or MRCPs, which was correctly decoded,

\[ TPR = \frac{TP}{TP + FN} \tag{1} \]

False positive rate (FPR) represents the percentage of MI or MRCPs, which was detected during both R and AO states,

\[ FPR = \frac{FP}{FP + TN} \tag{2} \]

False negative rate (FNR) denotes the percentage of both R and AO, which could be detected during MI or MRCPs state,

\[ FNR = \frac{FN}{FN + TP} \tag{3} \]

where \( TP = \) True positive, \( FP = \) False positive, \( TN = \) True negative, and \( FN = \) False negative.

To compare the binary classification results within each sit-to-stand/stand-to-sit-transition for MI and ME sessions, a paired t-test with unequal variances was used to determine the differences in the TPR, FPR, and FNR.

III. RESULTS

This section aims to depict the findings and the key contributions amplified by each experiment. Result A. reveals an investigated study of the MI and MRCP features; the ERSP and grand average MRCP waveforms are reported as the qualitative result. Result B. leads us to the possibility in using MI and MRCP signals for BCI systems, which reveals the classification performance of decoding MI and MRCP signals in term of offline and pseudo-online analysis.

A. Analysis of MI and MRCPs Features

ERD/S have been studied widely in MI related works as one of the markers of brain responses. Figure 5 demonstrates the grouped ERSP across 8 participants in MI state from both sit-to-stand (left panel) and stand-to-sit (right panel) transitions. The ERSP delineates ERD/S from the entire duration of the trials with respects to the baseline spectra from 4 to 40 Hz. All present ERSP values were significant compared to the baseline (\( p = 0.05 \)). In comparison between the ERSP from 11 channels in all trials of both transitions, a significant decrease of alpha band power, indicating ERD, mainly in the parietal and parieto-occipital regions for the AO state (4–8 s) was found. However, a sustained increase of alpha band power, indicating ERS, for the performing MI (9 s onward) in fronto-central and central regions was observed. Furthermore, we observed an atypical increase of ERS in the performing state of stand-to-sit compared to sit-to-stand transition.

Figure 6 illustrates the grand averages of the MRCPs (11 channels) across the 8 participants for the standing (left panel) and sitting (right panel) movements. The MRCP waveform demonstrates a negative and a positive amplitude variation from -1.5 to 1 s with respect to the actual movement onset. Time 0 s was defined as the actual movement onset, when the EMG signals overreached a pre-defined threshold amplitude. We observed the negative shape prior to the onset of actual movement (BP section), as well as the positive shape in MMP section. By considering the characteristic of the MMP section, we found a crucial difference between the amplitude pattern of the sit-to-stand and stand-to-sit transitions. There were appearances of the negative (the first 0.5 s period) and positive deflections (the last 0.5 s period) in MMP section for the stand-to-sit transition. On the other hand, only the positive deflection along with the MMP section of sit-to-stand transition was observed. The gray area along the MRCP waveforms denoted the SE of the BP and MMP amplitudes respective to each trial from the 8 participants. Scalp topographies were plotted to display the spatial pattern distribution of the variation in the MRCP amplitude over time.

For MRCPs, the scalp distributions represented the average amplitude (11 channels) across all participants (120 trials) for the sit-to-stand and stand-to-sit actions. Based on the topographies, we observed the brain activities during the intention of
movement by dividing the time interval into two phases. Prior to the beginning of the sitting and standing movements or during motor planning (-1.5 to 0 s), the brain activity displayed a slow-rising negative distribution in the central brain areas. After actual movement onset in ME session (0 to 1 s), the power of the spatial pattern returned from a negativity to positive spatial pattern.

B. Classification Performance of Decoding MI and MRCPs

The average performance across all participants of the proposed MI (R versus AO and AO versus MI) and ME for binary classification are displayed in Table I. The classification performance comparison between the sit-to-stand transitions and the stand-to-sit transitions was used for MI and MRCP decoding. The result of the MI (R versus AO and AO versus MI) revealed that the action of stand-to-sit transition significantly outperformed the sit-to-stand transition throughout the binary classification between AO and MI, \( t(231) = -2.54, p < 0.05 \), whereas the classification of R and AO did not exhibit significant differences. The result of ME failed to provide a statistically significant difference between these two transitions.

The TPR, FPR, and FNR results of pseudo-online analysis are displayed in Table II. The decoding results of the MI (R versus AO and AO versus MI) and ME during the sit-to-

---

**Fig. 5.** Neural responses to MI tasks. Grouped event-related spectral perturbation (ERSP) for frequencies between 4–40 Hz across the entire trials were pooled for (a) sit-to-stand and (b) stand-to-sit tasks in comparison to the baseline of the R state (-1–0 s). The time interval from 0–4 s corresponds to the R state, 4–8 s corresponds to the AO state, 8–9 s corresponds to the idle state, and 9 s onward corresponds to the performing state. The sampling rate was set to 600 Hz for visualization. All present ERSP values were statistically significant compared to the baseline (\( p = 0.05 \)).

**Fig. 6.** Grand average MRCP waveform (11 channels) across the 8 participants for the sit-to-stand (a) and stand-to-sit (b) transitions, from -1.5–1 s with respect to the actual movement onset. The scalp topographies display the spatial representation of the change in MRCP amplitudes over time.
The grand average FPR or false alarm rate from both transitions demonstrated that the coherent results from the ME are significantly higher than the MI (R versus AO and AO versus MI), with $t(238) = -12.62$, $p < 0.05$ for the sit-to-stand transitions and $t(230) = -13.94$, $p < 0.05$ for stand-to-sit transitions. On the other hand, the grand average TPR and FNR results did not indicate significant differences between these two sessions. The comparison of the grand average FPR, TPR and FNR are further discussed in Discussion C. In addition, Figure 7 illustrates the representation of the pseudo-online decoding results of MI (R versus AO and AO versus MI). The total number of windows throughout each trial was 56. The blue line indicates the AO onset, while the red line refers to MI onset. The light grey, dark grey, and black boxed indicate the decoding results for the R, AO, and MI classes respectively. Each window was decoded from the combined binary classification model between R versus AO and AO versus MI.

### IV. DISCUSSION

#### A. Characteristics of ERD/S During Action Observation and Motor Imagery

The current study investigated the role of action observation (AO) and motor imagery (MI) during the standing and sitting tasks. Specifically, the EEG potentials during resting (R) and the task performance (MI/ME) of sit-to-stand transition and stand-to-sit transitions were examined. Here, we introduced video presentations during the experiments for the simplification of the instruction, which distinguished the current study from the previous works. In our case, the videos of an actual person performing the acts of sit-to-stand and stand-to-sit were shown to the participants prior to task performing state. On the other hand, in other similar studies, participants were simply shown a few words or symbols as visual cues without being explicitly told about the particular actions that were instructed to perform. This could be the reason why ERD was observed during AO and ERS was observed during MI in our study, while ERD/S was only observed during MI in the previous studies [14], [15]. However, another study demonstrated greater ERD/S power during AO in comparison to MI, which supports our findings in terms of usefulness of the future treatments for patients who have limited MI ability [49].

Although we did not take into account the perspective-dependent action in our study, there were studies showing the effect of EEG rhythms from viewed self-performance [50], [51]. Specifically, the ERD/S response for observing a participant’s own hand was stronger than when the participants observed the movement of another person’s hand. Future research may take into account of perspectives in the design of their study, where participants can be asked to view the motor actions executed by themselves or by another person.

#### B. Decoding algorithms for standing and sitting tasks

To our best knowledge, the current study is the first to compare EEG rhythms during the sit-to-stand and stand-to-sit transitions. According to the AO versus MI in Table I, the mean accuracy was highest for the stand-to-sit transition at 82.73±2.38%, which was statistical higher than the sit-to-stand transition. This suggests that the MI activation during the stand-to-sit transition was distinguishable from the stand-to-sit transition, which corresponded to the characteristics of grand average MRCPs shown in Fig 6. The latency in the MRCPs of the stand-to-sit transition reflected the more difficult nature of this transition (i.e., lack of visual feedback towards the back as a person moves from standing to sitting) in comparison to the sit-to-stand transition, making it easier for the classifier to distinguish between AO and MI in this former transition. Indeed, previous studies have shown the effects of task complexity on ERD/S rhythms [52], [53].

These classification results were acceptable by comparing to the original study, which first introduced and employed FBCSP to classify the movement type into right hand activation and right foot activation with the mean accuracy level from 11 participants at 81.10±2.20% [44]. In the future, it is possible that our developed deep learning approaches can be used to increase the accuracy of EEG classification [54], [55].

#### C. Feasibility study and applications

The final aspect of the current study is to apply our findings for the future development of BCI based exoskeleton system used for the rehabilitation of patients with motor disorders. We performed the pseudo-online scheme on our continuous EEG rhythms across resting, AO, and MI. As reported in Table II, the comparison of the MI (R versus AO and AO versus MI) and ME showed that the TPR and FNR did not display any statistical difference. However, the FPRs or false alarm rates of sit-to-stand and stand-to-sit transitions during the MI (R versus AO and AO versus MI) were significantly lower than those in the ME session. As EEG rhythms from AO and MI were more feasible than those from the ME session, the experimental protocol by the current study will be suitable for BCI-based exoskeleton systems for rehabilitating patients with motor disorders of the lower limbs. For example, MI

#### TABLE I

| Subject ID | MI Session R vs. AO | ME Session AO vs. MRCPs |
|------------|---------------------|-------------------------|
|            | sit:std std:std     | std:std std:std         |
| S1         | 71.82 84.24         | 85.76 95.45             |

signal has been found to facilitate the operation of lower limb exoskeleton when the classification accuracy of MI patterns, and even motor intention, is high [56]–[59].

### V. Conclusion

In this paper, we are the first to investigate the possibility of combining action observation (AO) and motor imagery (MI) as a brain-computer interface (BCI) system (e.g., exoskeleton-based rehabilitation). We created a behavioral in which the participants were instructed to perform both AO and motor imagery (MI)/motor execution (ME) in regard to the actions of sit-to-stand and stand-to-sit. The pattern discrimination revealed that ERD responded during AO, and ERS responded during MI at the alpha band across the sensorimotor area. We obtained promising experimental results from both offline and pseudo-online analysis by using leave-one(trial)-out cross-validation (LOOCV) scheme. The integration of the filter bank common spatial pattern (FBCSP) and support vector machine (SVM) performed well in decoding the neural intentions between AO and MI for both offline and pseudo-online analysis. Together, our results suggest the feasibility of using the future exoskeleton-based rehabilitation that combines both AO and MI.

### TABLE II

TPR, FNR, and FPR results (in %) from MI and ME sessions with personalized pseudo-online analysis. Bold and * represents the number which was significantly higher than the other tasks, $p < 0.05$

| Subject ID | Sit-to-stand | | | Stand-to-sit | | |
|---|---|---|---|---|---|---|
| | TPR | FPR | FNR | TPR | FPR | FNR |
| | MI | ME | MI | ME | MI | ME | MI | ME | MI | ME | MI | ME |
| S1 | 69.63 | 62.89 | 7.54 | 37.22 | 30.37 | 37.11 | 79.26 | 85.33 | 8.60 | 23.44 | 20.74 | 14.67 |
