**Motivation:**
To keep up with the scale of genomic databases, several methods rely on local sensitive hashing methods to efficiently find potential matches within large genome collections. Existing solutions rely on Minhash or Hyperloglog fingerprints and require reading the whole index to perform a query. Such solutions can not be considered scalable with the growing amount of documents to index.

**Results:**
We present NIQKI, a novel structure using well-designed fingerprints that lead to theoretical and practical query time improvements, outperforming state-of-the-art by orders of magnitude. Our contribution is threefold. First, we generalize the concept of Hyperminhash fingerprints in \((h, m)\)-HMH fingerprints that can be tuned to present the lowest false positive rate given the expected sub-sampling applied. Second, we provide a structure able to index any kind of fingerprints based on inverted indexes that provide optimal queries, namely linear with the size of the output. Third, we implemented these approaches in a tool dubbed NIQKI that can index and calculate pairwise distances for over one million bacterial genomes from GenBank in a matter of days on a small cluster. We show that our approach can be orders of magnitude faster than state-of-the-art with comparable precision. We believe that this approach can lead to tremendous improvement allowing fast query, scaling on extensive genomic databases.

**Availability and implementation:**
We wrote the NIQKI index as an open-source C++ library under the AGPL3 license available at https://github.com/Malfoy/NIQKI. It is designed as a user-friendly tool and comes along with usage samples

**Introduction**

Historically, genomic databases such as GenBank are growing exponentially\textsuperscript{1}. Lower sequencing costs and required investment, broader access to sequencing technologies, and breakthrough in genome assembly practices will surely fuel the explosion of available genomes in a near future. While those data are still widely unprocessed the ability to explore and delve into such rich archives presents countless applications (1, 2) Allowing to query such database at a reasonable cost is a growing research subject (3–6). To avoid relying on computation-intensive steps, a good way to approximate the similarity of two sequences is to represent them as a set of \(k\)-mer (sub-word of length \(k\)) and compare their \(k\)-mer contents. Namely, the fraction of shared \(k\)-mer, that corresponds to the Jaccard index was found to be a good proxy for Average Nucleotide Identity (7) between genomes. Given the scale of such collections, indexing complete genomes quickly become prohibitively expensive. When searching for broad matches between large genomic sequences such as genomes, dimension reduction techniques can be used to reduce the computational burden.

Minhash (8) is a very resource-efficient technique able to estimate the Jaccard index between two sets. Minhash constructs a sketch of \(S\) fingerprints chosen from the hashed elements of a given set (e.g., selecting the smallest hash values). The interesting property of such sketches is that the Jaccard index between such sketches is an approximation of the actual Jaccard index of the two sets they represent. This way the Jaccard index can be estimated by comparing two sketches of size \(S\) that can be orders of magnitude smaller than the actual cardinality of the indexed sets.

Three main variants of Minhash have been proposed.

\textit{S hash functions:} Each element is hashed using \(S\) distinct hash functions \(h_1 \ldots h_S\), the sketch is composed of the smallest hash output by each hash function. The sketches can be compared in \(\Theta(S)\) and constructing sketches is \(\Theta(N.S)\)

\textit{S minimal values:} Each element is hashed using a single hash function \(h\), the sketch is composed by the \(S\) smallest hashes output by \(h\). The sketch construction is reduced to \(\Theta(N \log(S))\) but the sketch comparison is \(\Theta(S \log(S))\)

\textit{S partitions:} Each element is hashed using a single hash function \(h\), the hash value are split into \(S\) partition according to their first bits, the sketch is composed by the minimal element of each partition. The sketch construction is reduced to \(\Theta(N)\) and the sketch comparison to \(\Theta(S)\).

While \(S\) partition can seem optimal, some partitions can be empty if no hashes start with a given prefix. Some process subbed densification (9) aimed to cope with this problem by using other partition data to fill empty partitions.

\textsuperscript{1}https://www.ncbi.nlm.nih.gov/genbank/statistics/
The other parameter of a Minhash sketch is the size of each stored hash. Usually, a "large" hash size (e.g. 32 bits) is used to avoid the risk of collisions or saturation. Collisions occur when two different keys have the same hash value, leading to false-positive hits. Since the smallest hash values are kept, all fingerprints tend to zero. On the zero value attained, it can no longer change, we call such fingerprints saturated. Comparison of saturated sketches can report a large amount of false-positive hits.

However, since the minimal values are kept, the first bits of each fingerprint may contain a large amount of low-informative zeroes. To take advantage of such observation the b-bit Minhash (10) variation only keeps the b lowest bits to reduce the sketches sizes by reducing the fingerprints sizes. It can either improve the memory footprint of sketches or improve their accuracy by increasing the number of fingerprints used for the same amount of memory.

Those techniques were successfully applied in bioinformatics to index and compare genomes databases. Mash (7) implemented S’ minimal values and Bindash (11) implement S partitions , b-bit Minhash with optimal densification. Such work showed that genomes and whole sequencing datasets could be precisely compared by using sketches orders of magnitude smaller than their amount of distinct k-mers leading to tremendous performances improvement when working at a large scale.

An alternative to Minhash fingerprint is Hyperloglog (12) fingerprints. Instead of storing the whole hash, Hyperloglog fingerprints store its log value (e.g. the position of the leading 1). The interest of such fingerprints is twofold, they are very small, a 64bits hash needs a 6bits Hyperloglog fingerprint (since $2^6 = 64$) and as hard to saturate as their associated hashes. In practice, 6 bits seem enough to cover most real-world cases as 64bit hashes seem unlikely to be saturated. The downside is that their collision rate is very high. This fact can be leveraged by using a large number of fingerprints. Dashing (13) showed that large S’ partitions sketches of Hyperloglog fingerprints can lead to very precise estimations of Jaccard index between genomes.

Interestingly another approach tried to benefit from the trailing zeroes by combining the b-bit Minhash and Hyperloglog ideas. Hyperminhash (14) build a fingerprint from a given hash using 6 bits to encode the first run of zero (which is equivalent to a Hyperloglog fingerprint) and combine them with the lowest 10 bits (which is equivalent to a b bit Minhash fingerprint) to obtain a 16bits fingerprints. The interest of this sketch is to be very hard to saturate, due to the Hyperloglog fingerprint, and to limit the number of collisions with the additional Minhash bits. Such fingerprint can be seen as an efficient lossy compression of the hash value that represents more than 16 bits from the hash (if the run length of zero is longer than 6).

In bioinformatic, such fingerprint indexes have numerous applications such as very fast clustering or phylogeny construction from large genome collection, finding potentially related genomes from assembled contigs or sequence of interest, quantification of a given gene, strain, or species in databases etc... Their main feature is to be able to find possible matches for a query sequence inside a database, acting as filters to focus only on relevant entries. They do so by efficiently estimating similarities between query and indexes sequences.

The main bottleneck of existing methods is that a query requires the queried sketch to be compared to all sketches present in the database. In that sense, the query is $O(NS)$ with $N$ the number of indexed entries. With the exponential growth of available genomic resources, it simply cannot be considered scalable. To cope with this algorithmic problem we design a structure able to perform queries in $\Theta(\#hits)$ where $\#hits$ is the number of fingerprint hits between the queried sketch and the indexed sketches. Since the expected output of a query is a list of genomes identifier associated with a number of hits (or an approximation of the Jaccard index) we can consider our query time as close to optimal.

However such structure presents an overhead exponential with the fingerprint size. For this reason, we are extremely attentive to using powerful but small fingerprint sizes. To do so we generalize the Hyperminhash fingerprint and introduce $(h,m)$-Hyperminhash fingerprints that cover both Minhash and Hyperloglog cases and provide an analysis to select the best fingerprint for a given use case.

**Methods**

**Index structure.** To generalize the concept of indexing a sequence of fingerprints as Hyperminhash, b-bit Minhash, or Hyperloglog, we introduce the notion of sketches. In all the following, we combine bit-vectors of size $n$ and integers of $\{0,\ldots,2^n-1\}$.

Let $S$, $W$ and $N$ be three integers. A sketch $p_i$ of size $S$ is a sequence of $S$ fingerprints where a fingerprint is an element between 0 and $2^W - 1$, i.e. $p_i = f_{i,1} \ldots f_{i,S}$ where $\forall j \in \{1, \ldots, S\}$, $f_{i,j} \in \{0, \ldots, 2^W - 1\}$. We present a new data structure to index a set $B = \{p_1, \ldots, p_N\}$ of $N$ sketches where we want to optimize the time complexity of the query $\text{find}_\text{hits}(B, p', m)$ which corresponds to find all the sketches $p_i = f_{i,1} \ldots f_{i,S}$ of $B$ such that $\{|j \in \{1, \ldots, S\} | f_{i,j} = f'_{j}\} \geq m$ with $p' = f'_1 \ldots f'_S$ a sketch and $m$ an integer.

Instead of index sketch by sketch of sets $B$ by column et for each column $j$ between 1 and $S$, we denote by $B_j$ the sequence of fingerprints $f_{1,j} \ldots f_{N,j}$. Unlike previous approaches, our scheme handles each column $B_j$ independently by grouping the indices with the same fingerprint on this column. Indeed, for each column $j$ between 1 and $S$, we index in a vector the sets $X_{j,0} \ldots X_{j,2^W -1}$ where for all $l \in \{0, \ldots, 2^W -1\}$, $X_{j,l} = \{i \in \{1, \ldots, n\} | f_{i,j} = l\}$. As $X_{j,0} \ldots X_{j,2^W -1}$ is a partition of $\{1, \ldots, N\}$, we have $O(N + 2^W)$ elements. By constructing two tables, the first of size $N$ and the second of size $2^W$, we can implement the sets $X_{j,0} \ldots X_{j,2^W -1}$ by using only $(N + 2^W).\log(N)$ bits and with a time complexity optimal of the query for $\text{find}_\text{hits}(B_j, f'_j, 1)$, i.e. in $O(\{|i \in \{1, \ldots, N\} | f_{i,j} = f'_{j}\})$. 

2 | bioRxIV

Limasset et al. | NIQKI
By using a bit vector of size \(N + 2^{W + 1}\), and \(\text{rank}\) and \(\text{select}\) operations, we can use only \(N,(\log N + 1) + 2^{W + 1} + o(N + 2^{W + 1})\) bits to store \(X_{j,0}\ldots X_{j,2^{W - 1}}\) with the same time complexity optimal of the query. Indeed, we can compute in constant time the \(\text{rank}\) and \(\text{select}\) operations by adding \(o(N + 2^{W + 1})\) space (15). As \(\text{find\_hits}(B, p', m) = \{i \in \{1, \ldots, N\} \mid \sum_{j=1}^{N} \text{find\_hits}(B_j, t'_j, 1)(j) \geq m\}\), by computing all the \(\text{find\_hits}(B_j, t'_j, 1)\), we can compute \(\text{find\_hits}(B, p', m)\).

Finally, we have a complexity for \(\text{find\_hits}(B, p', m)\) of \(O(\#\text{hits})\) in time and of \(S.N.(\log N + 1 + o(1)) + S.2^{W + 1}.(1 + o(1))\) bits in space.

Besides those algorithmic improvements, we argue that performing queries by partition presents several advantages. One advantage of this processing partition by column is the possibility to stop queries that can not find high-scoring matches. If we are looking for a minimum of \(m\) shared fingerprint among \(S\) to report a match, if after \(B_{|S| - j}\) no sketches share at least \(m - j\) fingerprints, that query can be stopped as no matches can reach the minimal score. If not using the densification technique, empty partitions could also be skipped.

As, for our case, a sketch represents a genome and the fingerprints come from the set of \(k\)-mers of this genome, one possible mechanism presented in (16) inspired by (17) is to insert the \(k\)-mers of a given partition in a Bloom filter (or any set structure) to "protect" each partition from alien \(k\)-mers. In such a scheme if the selected \(k\)-mer is not in the partition set, the partition is skipped as we know that the \(k\)-mer was not inserted in the partition and that any fingerprint hit would be a false positive.

**Proposed practical structure.** In a trade-off favoring code simplicity and throughput over memory footprint, we choose to use dense addressing to index our partitions. This way our index has an overhead of \(\Theta(S.2^{W})\) as we allocate \(S.2^{W}\) vectors to represent all possible values of each partition. Once the index created, inserting the \(n\)th sketch \(p_n = f_1\ldots f_S\) is inserting \(n\) in the vector \(f_i + i.2^{w}\). The inserted elements cost \(\Theta(N.\log(N))\) space and each partition can be queried optimally in \(\Theta(\#\text{hits})\). If this approach presents a costly overhead, its interest is that query a sketch performs at worst \(S\) "costly" random access. We argue that in practice, using relatively small well-designed fingerprints, our scheme can perform very fast queries with a reasonable memory footprint.

**Optimal Hyperminhash fingerprint.** Since our proposed scheme presents an overhead exponential with \(W\), we need to rely on very space-efficient fingerprints and make the most of each bit. When building a fingerprint database, the users tune the sketches' size according to the expected genome sizes they index along with the needed precision according to their application. This parameter also changes the fingerprint values as we expect each fingerprint to be the minimum across \(\approx \frac{2^{W}}{\text{genome\_size}}\) that we call the sub-sampling value. In the section, we argue that different sub-sampling values call for different fingerprints. In this part, we present a parametric fingerprint that generalizes Hyperminhash, b-bit minhash, and Hyperloglog and give a method to fix this parameter to optimize the false positive rate for a given fingerprint size.

For a bitvector/hash \(B\) of size \(n\) and two integers \(h\) and \(m\) such that \(h + m = W\), the \((h, m)\)-hyperminhash fingerprint of \(B\), denoted by \(\text{HMH}_{h,m}(B)\), is the bitvector of size \(h + m\) where the \(h\) first bits correspond to the NOT of the number of zeros at the beginning of the prefix of \(B\) of size \(2^h - 1\) and the \(m\) last bits are the last \(m\) bits of \(B\), i.e.

\[
\text{HMH}_{h,m}(B) = \max(2^h + \lfloor \log(B) \rfloor - n, 0) \times 2^m + (B \bmod 2^m)
\]

For a set \(X\) of bitvectors of size \(n\), the \((h, m)\)-hyperminhash fingerprint of \(X\) is the minimum value of the \((h, m)\)-hyperminhash fingerprint of \(B\) for all the bitvectors \(B\) of \(X\), i.e. \(\text{HMH}_{h,m}(X) = \min_{B \in X} \text{HMH}_{h,m}(B)\).

Our goal is to find the pair \(h, m\) where \(h + m = W\) which gives us the most space-efficient fingerprint, i.e. the fingerprint which covers the most larger interval of values. One way to compute this space-efficiency is for a threshold \(\varepsilon\) of \([0, 1]\), to compute \(a_{h,m} = b_{h,m} - a_{h,m} + 1\) which is the size of the interval \(\{a_{h,m}, \ldots, b_{h,m}\}\) where

\[
a_{h,m} = \max_{k \in \{0, \ldots, 2^{w - 1}\}} \left(\mathbb{P}[\text{HMH}_{h,m}(X) \leq k] \leq \frac{1}{2}\right)
\]

\[
b_{h,m} = \min_{k \in \{0, \ldots, 2^{w - 1}\}} \left(\mathbb{P}[\text{HMH}_{h,m}(X) \leq k] \geq 1 - \frac{1}{2}\right)
\]

and thus \(\mathbb{P}[a_{h,m} \leq \text{HMH}_{h,m}(X) \leq b_{h,m}] \leq 1 - \varepsilon\).

To begin, if \(n < 2^{h} - 1 + m\), some bits can be used by the prefix and by the suffix of the fingerprint due to the overlap, and thus it is not space-efficient. Indeed, we can prove that the number of fingerprint values that are not reached is equal to \(2^{m} \times (2^{h} - 1 + m - n)\). For this reason, we take in all the following \(n \geq 2^{h} - 1 + m\).

For an integer \(k\) of \([0, \ldots, 2^{h} + m]\), we denote by \(H(h, m, k)\) the number of \(B\in\{0, \ldots, 2^{n} - 1\}\) such that \(\text{HMH}_{h,m}(B) = k\). As \((h, m)\)-hyperminhash is an increasing function because if \(B \leq B'\), we have \(\text{HMH}_{h,m}(B) \leq \text{HMH}_{h,m}(B')\), by counting, we can show that \(H(h, m, k) = 2^{n - 2^{h} + 1 - m + \max(0, \lfloor \frac{k}{2^{m}} \rfloor - 1)}\). Indeed, each \(B\) of \([0, \ldots, 2^{n} - 1]\) such that \(\text{HMH}_{h,m}(B) = k\) has the suffix of length \(m\) and the prefix of length \(2^{h} - 1 - \max(0, \lfloor \frac{k}{2^{m}} \rfloor - 1)\) which are fixed.
As $\Pr[\text{HMH}_{h,m}(X) \leq k] = \sum_{i=0}^{k} \Pr[\text{HMH}_{h,m}(X) = i]$, it is enough to know the value of $\Pr[\text{HMH}_{h,m}(X) = k]$. As $\sum_{i=0}^{k} H(h,m,i) = 2^{n-2^h+1-m} \times \sum_{i=0}^{k} n^{\max(0,\lfloor k \div 2^m \rfloor -1)}$, if $k < 2^m$, $\sum_{i=0}^{k} H(h,m,i) = k \times 2^{n-2^h+1-m}$. Otherwise,

$$
\sum_{i=0}^{k} H(h,m,i) = 2^{n-2^h+1-m} \times \sum_{i=0}^{k} n^{\max(0,\lfloor i \div 2^m \rfloor -1)}
$$

$$
+ \sum_{i=2^m}^{k} n^{\max(0,\lfloor i \div 2^m \rfloor -1)} + \sum_{i=\lfloor \frac{k}{2^m} \rfloor \times 2^m}^{k} 2^{\max(0,\lfloor i \div 2^m \rfloor -1)}
$$

$$
= 2^{n-2^h+1-m} \times (2^m \times 2^0 + 2^m \times \sum_{i=0}^{2^m} 2^i + \sum_{i=\lfloor \frac{k}{2^m} \rfloor \times 2^m}^{k} 2^{\lfloor i \div 2^m \rfloor -1})
$$

$$
= 2^{n-2^h+1-m} \times (2^m + 2^{\lfloor \frac{k}{2^m} \rfloor -1+m} - 2^m) + ((k \mod 2^m +1) \times 2^{\lfloor \frac{k}{2^m} \rfloor -1})
$$

$$
= 2^{n-2^h-m+\lfloor \frac{k}{2^m} \rfloor} \times (2^m + (k \mod 2^m +1))
$$

For the sake of completeness, we added all the calculations of $\sum_{i=0}^{k} H(h,m,i)$, but the only thing one needs to remember is that it can be calculated in constant time. Besides, we have

$$
\Pr[\text{HMH}_{h,m}(X) = k] = \Pr[\text{HMH}_{h,m}(X) > k - 1] - \Pr[\text{HMH}_{h,m}(X) > k]
$$

$$
= \frac{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k-1} H(h,m,i)}{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k} H(h,m,i)} - \frac{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k} H(h,m,i)}{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k} H(h,m,i)}
$$

We can extend this formal definition to the probability of interval $[a,\ldots,b]$, i.e.

$$
\Pr[a \leq \text{HMH}_{h,m}(X) \leq b] = \frac{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k} H(h,m,i)}{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k} H(h,m,i)} - \frac{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k} H(h,m,i)}{C^{\lfloor |X| \rfloor}_{2^n} - \sum_{i=0}^{k} H(h,m,i)}
$$

By approximating the value of $\Pr[\text{HMH}_{h,m}(X) \leq k]$ by $1 - \left(\sum_{i=0}^{k-1} \frac{H(h,m,i)}{2^m}\right) |X|$, we can give an approximation of $\alpha_{h,m}$ and $\beta_{h,m}$ for a threshold $\varepsilon$ of $[0,1]$ in $O(1)$:

$$
\alpha_{h,m} \approx \begin{cases} 
(1 - \left(1 - \frac{\varepsilon}{2}\right) \frac{1}{|X|}) \times 2^{m+2^h} - 1 & \text{if } (1 - \left(1 - \frac{\varepsilon}{2}\right) \frac{1}{|X|}) < 2^{1-2^h} \\
(\log_2(1 - \left(1 - \frac{\varepsilon}{2}\right) \frac{1}{|X|}) + 2^h - 1) \times 2^m + 1 & \text{Otherwise}
\end{cases}
$$

and

$$
\beta_{h,m} \approx \begin{cases} 
(1 - \left(\varepsilon\right) \frac{1}{|X|}) \times 2^{m+2^h} - 1 & \text{if } (1 - \left(\varepsilon\right) \frac{1}{|X|}) < 2^{1-2^h} \\
(\log_2(1 - \left(\varepsilon\right) \frac{1}{|X|}) + 2^h - 1) \times 2^m + 1 & \text{Otherwise}
\end{cases}
$$

As shown in Figure 1a, the choice of the good fingerprint depends on the size of the sub-sampling. By dichotomic search, we can compute each exact value $c_{h,m}$ in $O(|X| \times |W|)$ and thus we can find the pair $h,m$ which maximizes $c_{h,m}$ in $O(|X| \times |W|^2)$. In practice, we use the approximation value of $c_{h,m}$ to compute an approximate optimal pair $h,m$ in $O(W)$. The correspondence between the theoretical optimal fingerprint and the fingerprint with the minimum false positive values in practice justifies the relevance of our study (see Figure 1).

**Implementation details.** Our proof of concept is dubbed NIQKI (stand for Next Index to Query k-mer Intersection) is opensource and available on Github [https://github.com/Malfoy/NIQKI](https://github.com/Malfoy/NIQKI). In this section, we detail some practical aspects of this implementation.

Our NIQKI index is technically able to index any kind of fingerprint. In practice, from a given fingerprint size (12 by default), we use the best possible (h,m)HMH fingerprint when the user specifies an expected genome size or a regular Hyperminhash
fingerprints if the expert user precise the size of the Hyperloglog fingerprint. If no input is given, we use a default Hyperloglog fingerprint of four.

NIQKI is written in C++ and parallelized with straightforward OpenMP instructions. Each thread inserts or queries a set of sequences independently. For insertion, a mutex array is used to protect our vectors from double writing. For performance purposes, we chose to use 64-bit hashes as they provide a low collision chance at the hash level in practice while using efficient 64 bits integers. For the same reason, we use a Xorshift (18) hash function are they are found good enough in practice while being extremely cheap to compute. For code simplicity and performances aspect, the sketches sizes are necessarily a power of

![Graphs showing theoretical probabilities and intervals of presence](image_url)
two. Like Dashing we ask the user to enter $\log_2(S)$ instead of the actual sketch size.

Our implementation can take as input any classical sequence format: fastq, fasta, or multiline fasta files gzipped or not. The input is either a file of files where each file is an entry to index (or query) or a file where each sequence is a separate entry. We also provide a way to download genomes directly from NCBI from an accession list (that can be generated following NCBI instruction\(^2\)). The corresponding sequences are downloaded and directly inserted in the index in a streaming fashion without using any disk operation.

Indexes can be dumped and loaded from the disk for later use. This allows users to keep a small index on a disk instead of a large files collection and to avoid reading all files to reload a given index.

By default, our implementation delivers a gzip-compressed sparse output to limit disk usage. We provide a pretty printer to parse such a file and an option to directly output (larger) human-readable output.

A common use of such a genome index is to compute all pairwise distances between them by comparing the index with itself. An efficient way to do this with our approach is to check every vector of our index and increment the score of each genome pair present in the vector. This technique, while very fast in theory, requires storing the whole score matrix of size $N^2$ in memory to be efficient. Henceforth this behavior can be interesting when a large amount of memory is available or when the number of genomes is not too large. Optimization relying on buffer keeping the matrix on disk manage to dissipate this memory footprint problem at the expense of several passes on the index. In the following benchmarks, the pairwise distances are computed without using the fact that the input is the indexed data itself, where competitors use this information to avoid reading the input file several times or to avoid computing the lower-left side of the symmetrical matrix.

Results

Fingerprint impact. As we previously evaluated the impact of the size of the Hyperloglog fingerprint, we now aim to evaluate the impact of the fingerprint size itself. The fingerprint size can be seen as the main parameter of our index along with the amount of fingerprint used because our index has a $\theta(S,2^W)$ memory overhead. More importantly, the fingerprint size will impact the amount of false-positive hits where two distinct hashes in compared sketches get the same fingerprint. Such false-positive hits over-estimate the similarity and may negatively impact downstream results by reporting irrelevant matches. To access the number of false positives found in practice, we created a synthetic dataset of one thousand randomly generated genomes of 10 million bases that share no $k$-mers. We computed the pairwise distances between all those "genomes" and counted the number of hits between unrelated genomes as false positives. More specifically we computed sketches of size 4,096 from each 10 megabases synthetic genome with fingerprint sizes varying from 4 to 18 with a constant Hyperloglog fingerprint size equal to four. We present the false-positive rates found in practice along with the memory used by our index for such experiment using various fingerprint sizes in Figure 2. As expected, we observe the false positive rate decreasing exponentially as we increase the size of the fingerprint. We observe that a very low false-positive rate can be obtained with low fingerprint size, from $W = 12$ the rate is below $10^{-3}$ and from $W = 15$ below $10^{-4}$.

Accuracy analysis. To analyze further the precision of our approach, we compared the result of NIQKI with the state of the art on a real dataset composed of one thousand bacterial genomes from Refseq. In this experiment, we computed the pairwise distances between all genomes with our approach and compared those results with Dashing using a very large number of fingerprints (1 million) as the ground truth. In a first experiment reported in Figure 3 we plot the correlation between NIQKI and Dashing estimations using different amounts of fingerprint (namely $S = 65536, S = 4096$ and $S = 256$) while using a constant fingerprint size ($W = 12$). As described in the theoretical analysis of the related studies, a smaller amount of fingerprints results in larger error bounds. We observe than NIQKI obtain a strong correlation with Dashing output even with a very low amount of fingerprint. This means that even small sketches can lead to rough estimations that can be improved by using larger sketches where the error bound can be extremely small as in the standard approaches.

In a second experiment reported in figure 4 we used different fingerprint sizes (namely $W = 8, W = 6$ and $W = 4$) with a constant fingerprint number($S = 65536$).

Due to the large number of fingerprints, we observe very small errors bounds, but due to the false positive rate, we observe that all indices are overestimated. The expected overestimation is $\approx (1 - J) * FP_{Rate}$ where $J$ is the Jaccard index between the two sequences and the observed pattern goes accordingly with this projection.

This experiment shows that the use of fingerprints as small as 8 seems reasonable in practice for such an index. When dealing with a low Jaccard index, the false positive rate could still impact the results and a larger fingerprint should be used. We fixed the default fingerprint size to 12 as it provides very low false positives and a reasonable memory overhead.

Performance analysis. In this section, we display how our index can scale on synthetic and real datasets compared to the two most used tools of the state-of-the-art Mash and Dashing. All experiments were performed on a single cluster node running with Intel(R) Xeon(R) CPU E5-2420 @1.90GHz with 192GB of RAM and Ubuntu 16.04, with a timeout of 48hours. Bindash was not included in our benchmark because it is not able to compute a distance matrix from a file of files directly.

Fig. 2. Impact of fingerprint size on false-positive rate and memory usage when indexing and comparing one thousand synthetic genomes of 10 megabases against themselves. Here the Hyperloglog fingerprint is kept constant ($H = 4$) and 4,096 fingerprint are used per genome.

Fig. 3. Impact of increasing sketch sizes. We display the correlation between NIQKI with varying sketch size and Dashing using one million fingerprints on one thousand bacterial genomes from RefSeq. Here the fingerprint size is kept constant ($W = 12$).

All state of the art tools present a $O(S.N)$ query time (or $O(S.\log(S)).N$) if $S$ minimum Minhash is used) as a query sketch have to be compared to each indexed sketch. In contrast, our index presents a query time linear with the number of hits. It can be $O(S.N)$ in the worst case where all genomes are identical and can be $O(S)$ in the best-case scenario where an alien entry is completely dissimilar with the indexed genomes (ignoring false positives).

To show those two regimes we choose to perform a first "idealistic" benchmark with randomly generated genomes sharing no $k$-mers which display the best case of our index. In a second experiment, we compare those results to a real database composed of GenBank genomes. To build such an index we downloaded all Genbank bacterial assemblies (1,042,611) and randomly selected genomes from this pool. We want to point out that such a database is highly redundant, for instance, it contains 142,568 assemblies of the Escherichia coli organism. As such it constitutes a stress case for our index as each query associated with Escherichia coli should report a very large part of the indexed genomes among its matches.

In Figure 5 we ran Dashing, Mash, and NIQKI to compute pairwise distance on randomly generated genome collection of growing sizes and report the mean CPU time per entry and RAM usage. Because of the quadratic aspect of computing all pairwise distances, we choose to report the mean time required per entry by dividing the total running time by the amount of entry to improve results readability. To provide a fair comparison we choose parameters such as each tool to allocate the same memory per entry. Mash used 65,536 32 bits Minhash fingerprints, Dashing used 262,144 8 bits Hyperloglog signature and
Fig. 4. Impact of increasing fingerprint sizes. Correlation between NIQKI with varying fingerprint size and Dashing using one million fingerprints on one thousand bacterial genomes from RefSeq. Here the sketch size is kept constant ($S = 65536$).

Fig. 5. Benchmark on synthetic genomes. We report the CPU time divided by the number of entry and the total memory footprint for various collection sizes. Mash is plot in red, Dashing in green and NIQKI in blue.

NIQKI used 65,536 32 bits genome identifiers and used the default fingerprint ($W = 12$). We observe that both Mash and Dashing runtime grow following a quadratic evolution which is expected as computing all pairwise distances needs $\Theta(SN^2)$. The growth runtime of NIQKI is roughly linear and can become orders of magnitude faster than the state of the art.

In Figure 6 we perform the same experiment on a realistic database constituted from bacterial GenBank genomes. We observe that Mash and Dashing deliver similar performances on synthetic and real datasets. The main difference is due to the fact that the mean size of bacterial genomes is around 5 megabases while the generated genomes were 10 megabases long. NIQKI results on small databases are similar to the synthetic cases, but a superlinear growth can be observed on the largest collections. However, despite this observation NIQKI is still able to be orders of magnitude faster than state-of-the-art tools while using a comparable amount of memory. For example, the largest Mash experiment used 773 CPU hours on 50k genomes where NIQKI used only 15 CPU hours. The largest Dashing experiment used 645 CPU hours on 100k genomes where NIQKI used only 30 CPU hours. We extrapolate that Dashing or Mash would need more than ten thousand CPU hours to handle 500k genomes while NIQKI used 166 CPU hours. On the downside, because of its large overhead NIQKI uses more memory than the other approaches on small collections and is slightly more memory expensive than Dashing on larger databases.

Indexing Genbank bacterial genomes. To access our approach scaling ability scalability we choose to index and compute pairwise distance on all bacterial genomes from GenBank. This dataset represents more than one million genomes, counting more than 5 tera-nucleotides or more than 1 terabytes of gzipped fasta files. We choose to evaluate the cost of such an operation with varying the amount of indexed minimizer that linearly impact the memory cost and the running time of our approach. We choose to keep the memory overhead constant ($O(2^W \log_2(S))$) to ensure a fair memory comparison and raised the fingerprint size accordingly. We report the CPU time and Wall clock time along with the memory usage required for those experiments in Table 1. We observe that we can index and compute pairwise distance on such a database with medium-sized sketches in a couple of days with a reasonable memory footprint. If the indexing time is roughly constant and dominated by reading the input, we observe that the query time grows linearly with the sketch size (plus a “reading” time constant cost). We want to recall that most of the query computational time is due to the database’s redundancy that generates a large number of matches for any queries. For comparison, on a simulated dataset of one million random synthetics genomes indexed with 4096 fingerprints the query time only lasted 12 hours instead of 38 hours for the Genbank database.
Conclusions and future work

We showed that the use of inverted indexes on partitioned sketches leads to algorithmic improvement of fingerprint queries that can reduce running time by orders of magnitude with comparable precision. Theoretically, our proposed structure query is $O(#\text{hits})$ compared to $O(S.N)$ for the state of the art. This structure came with a memory cost as our index uses $O(S(N\log N + 2^W))$ bits instead of $O(S.N.W)$. In practice, we showed that even a straightforward implementation could index small fingerprints in a very efficient manner while providing results comparable to the state of the art. We showed that on both idealistic synthetic databases and on real-world redundant databases that our approach could provide orders of magnitude faster queries on large instances with comparable memory footprint. We also demonstrated our index capacity to index and query all bacterial genomes of Genbank (more than one million bacterial genomes) in a matter of days on a small cluster.

While our index can index any kind of fingerprints (Minhash, Hyperloglog, Hyperminhash) we aimed to provide the best possible fingerprints of a given size to limit the number of false positives. To do so we generalized the concept of Hyperminhash to take into account different sizes of Hyperloglog and Minhash fingerprints dubbed $(h,m)$-HMH fingerprints. Interestingly Minhash, Hyperloglog, and Hyperminhash fingerprints can be seen as particular cases of $(h,m)$-HMH fingerprints. We show that given an expected sub-sampling we can select the $(h,m)$-HMH fingerprint with optimal parameter the provide the lowest false positive rate and confirmed this choice in practice. While improving false-positive rates, those well-designed fingerprints come without computational or memory cost and as such could be used to improve existing sketching methods.

On the practical aspect, our implementation still misses user-friendly features such as computing different metrics used in practice (Mash Index, containment index, or cardinality estimation) using advanced estimation methods. The different partition-based optimization described in the methods could also optimize query time in certain situations. Optimal sketches densification as used by binDash could also help to cope with empty partitions. Furthermore, our running time could be highly improved with the implementation of classical optimization techniques such as batched queries, the SIMD parallelism or vectorization, or practical optimization as computing only upper-half identifiers when comparing the index against itself. More importantly, our current implementation uses plain integers as genomes identifiers leading to high memory costs. As our vectors can be seen as lists of increasing integers, those could be compressed with delta-encoding or other high throughput compression technique (19). This way the index representation could be highly reduced with a limited impact on the runtime. While our proof of concept implementation is efficient, it tends to allocate a large amount of unused memory because of the heavy use of vectors. Other implementations could be made with different time/memory trade-offs. For example, the comparison of our approach with a Rank and the select-based index could be interesting.

On the theoretical aspects, our analysis of $(h,m)$-HMH fingerprint leads us to identify the need for an efficient fingerprint that presents smoother patterns to enable a larger range of possible hashes with or without estimation of the sub-sampling. On the fingerprint indexing problem, we showed that our partition query can be considered as optimal as its running time is linear with the size of the output. However, the classical usage is to ask for matches with a number of hits above a certain threshold. It would be interesting to investigate which indexes or algorithmic solutions would provide an optimal answer to this problem.

ACKNOWLEDGEMENTS

We want to thank Camille Marchet, Pierre Doignies, organizer and participant of the Bioinformatics: from Algorithms to Applications conference for their support and discussions on this project. The ANR SEQdigger supported this work.
