**Abstract**

**Background:** The presence of hydrogen peroxide (H2O2) producing *Lactobacillus* in the vagina may play a role in controlling genital HIV-1 shedding. Sensitive molecular methods improve our ability to characterize the vaginal microbiota; however, they cannot characterize phenotype. We assessed the concordance of H2O2-producing *Lactobacillus* detected by culture with quantitative PCR (qPCR) detection of *Lactobacillus* species commonly assumed to be H2O2-producers.

**Methods:** Samples were collected as part of a prospective cohort study of HIV-1 seropositive US women. Cervicovaginal lavage specimens were tested for *L. crispatus* and *L. jensenii* using 16S rRNA gene qPCR assays. Vaginal swabs were cultured for *Lactobacillus* and tested for H2O2-production. We calculated a kappa statistic to assess concordance between culture and qPCR.

**Results:** Culture and qPCR results were available for 376 visits from 57 women. Lactobacilli were detected by culture at 308 (82%) visits, of which 233 of 308 (76%) produced H2O2. *L. crispatus* and/or *L. jensenii* were detected at 215 (57%) visits. Concordance between detection of *L. crispatus* and/or *L. jensenii* by qPCR and H2O2-producing *Lactobacillus* by culture was 75% (kappa = 0.45).

**Conclusions:** Among HIV-1 seropositive women, there was a moderate level of concordance between H2O2-producing *Lactobacillus* detected by culture and the presence of *L. crispatus* and/or *L. jensenii* by qPCR. However, one-quarter of samples with growth of H2O2-producing lactobacilli did not have *L. crispatus* or *L. jensenii* detected by qPCR. This discordance may be due to the presence of other H2O2-producing *Lactobacillus* species.

**Keywords:** *Lactobacillus*, *Lactobacillus crispatus*, Lactobacillus jensenii, Bacterial vaginosis, Culture, Hydrogen peroxide, 16S rRNA gene

---

**Background**

Bacterial vaginosis (BV) and BV-associated organisms have been associated with an increased risk of HIV-1 RNA genital tract shedding [1,2]. Conversely, the presence of hydrogen peroxide (H2O2) producing lactobacilli in the vagina has been associated with a reduced likelihood of HIV-1 RNA shedding [2,3]. Thus, it is hypothesized that H2O2-producing lactobacilli may play an important role in controlling genital HIV-1 shedding. The development of sensitive molecular methods, such as 16S RNA gene polymerase chain reaction (PCR) assays, improves our ability to characterize the vaginal microbiota; however, they cannot characterize H2O2 production [4]. As cultivation-independent methods become more widely used, it is important to understand how these novel methods compare to traditional culture-based methods. *Lactobacillus crispatus* and *L. jensenii*...
**Methods**

We used samples collected as part of a prospective cohort study of HIV-1 seropositive women conducted from 2002–2007 in Seattle, WA and Rochester, NY. The institutional review boards at the University of Washington and University of Rochester approved the study and participants provided written informed consent. At enrollment, eligible women were 18–50 years old, HIV-1 seropositive and not pregnant. Women were not eligible to enroll if they had active substance abuse that would preclude their ability to participate in the study or if they had a hysterectomy. Participants had 4 study visits in the first year and 3 visits per year in subsequent years. Each study visit included a face-to-face interview to ascertain information on demographics, sexual behavior, medical use, and reproductive and medical history. Plasma was obtained for HIV-1 RNA quantification. A pelvic examination was performed with collection of vaginal swabs for diagnosis of vaginal infections and Lactobacillus culture. Vaginal fluid specimens were not collected if the participant was menstruating. Bacterial vaginosis was diagnosed from vaginal Gram stain using Nugent’s criteria [7]. Trichomonas vaginalis was detected by culture using the InPouch system (Biomed Diagnostics, White City, Oregon). The presence and quantity of Lactobacillus was assessed by vaginal culture on Columbia 5% sheep blood and Rogosa agar. Isolates from blood agar were grown in 5-10% CO2. Isolates from Rogosa agar were incubated anaerobically. All colonies with morphology suggestive of Lactobacillus on blood agar as well as any colonies growing on Rogosa were isolated and identified on the basis of colony morphology and Gram stain [8,9]. These isolates were subcultured on tetramethylbenzidine (TMB) agar containing horseradish peroxidase in order to assess hydrogen peroxide (H2O2) production [10,11].

Cervicovaginal lavage (CVL) was collected by washing the ectocervix and vaginal walls with 7 mL of 10 mM lithium chloride solution, which was then collected from the vaginal pool, spun at 800 g for 5 minutes to separate the epithelial cells and stored at ~80°C. Plasma and CVL HIV-1 RNA were quantified by an independently validated real-time PCR assay described previously [12], with a lower limit of detection of 30 copies/mL.

The frozen cell pellet from CVL was thawed and underwent DNA extraction with the MO BIO Bacteremia Isolation Kit (MO BIO Laboratories, Inc., Carlsbad, CA). Extracted DNA was tested by quantitative PCR using primers targeting the human 18S rRNA gene to validate that successful DNA extraction occurred and an internal amplification control PCR using exogenous DNA from a jellyfish gene was used to test for presence of PCR inhibitors [13]. Samples were then subjected to taxon-directed 16S RNA gene qPCR assays for the detection and quantification of L. crispatus and L. jensenii. Each assay had been validated previously and proven to be sensitive (to a level of 1–10 DNA copies/reaction) and specific (does not detect other bacteria at a concentration of 10⁶ copies/reaction) [14,15]. The assays used a TaqMan format and were run on an ABI 7500 Thermocycler (Applied Biosystems, Foster City, CA) or Eppendorf Mastercycler ep Realplex thermal cycler (Eppendorf, Westbury, NY). Negative assays were assigned a value at the lower limit of detection for that assay.

Based on the findings from our analysis of concordance, we conducted an exploratory analysis using broad range 16S rRNA gene PCR on a subset of culture isolates derived from samples with high quantities of H2O2-producing Lactobacillus by culture (≥10⁶ colony forming units [CFUs]), but with negative results for both L. crispatus and L. jensenii by qPCR in CVL. Lactobacillus isolates were retrieved from ~80°C storage and streaked to Rogosa agar and Columbia agar with 5% sheep blood. A repeat streak to fresh agar was performed in order to obtain new isolates for broad range PCR testing. Genomic DNA was extracted from single bacterial colonies, single colonies converted to a lawn of bacteria (patches), or streaks of colonies on plates using the BioStic Bacteremia DNA Isolation kit (MO BIO Laboratories, Inc., Carlsbad, CA). PCR was performed to amplify a portion of the bacterial 16S rRNA gene using combinations of the following broad range bacterial primers: 27 F bact (5’-AGAGTTTGATCMTGGCTCAG-3’), 338 F (5’-ACTCCTRCGGGAGGCAGCAG-3’), 806R (5’-GGACTACCAGGGTATCTAAT-3’) and 1407R (5’-GACGGGCGGTGWGTRCA-3’). A range of 10ul neat DNA to 1ul 1:10 diluted DNA was added to 50ul reaction. Thermal cycling consisted of pre-melting at 95°C for 2 minutes, followed by 25 cycles of melting at 95°C for 30 seconds, annealing at 55°C or 60°C for 30 seconds and extension at 72°C for 2 minutes, with a final extension at 72°C for 10 minutes. PCR products were cleaned using the 0.5–mL 100 K Amicon Ultra Centrifugal Filters (Millipore, Billerica, MA). The same PCR primers were used in the sequencing reactions using ABI Prism 3730xl DNA Analyzer and BigDye chemistry. Sequencher software (GeneCodes, Ann Arbor, MI) was used to assemble sequence data. Sequences of the isolates (~800 base pairs in length) were compared to known bacterial sequences.
in Genbank by BLAST algorithm. Identities of the isolates to known species was defined by having >98% sequence similarity.

We used descriptive statistics for planned and exploratory analyses and calculated a kappa statistic to assess concordance between culture and qPCR using Stata version 11.0 (StataCorp, College Station, TX).

**Results**

Culture and qPCR results were available for 376 visits from 57 women. The median number of visits per woman was 6 (interquartile range (IQR): 3–6; range: 1–15). The median age of participants at enrollment was 38 (IQR: 35–42) and 33 (58%) reported African-American race. The median CD4 count and plasma viral load was 417 cells/mm³ (IQR: <30–15, 850), respectively. Over half of women were on antiretroviral therapy at enrollment and the median quantity of H₂O₂+ was 1.0E + 10⁷ gene copies per sample (IQR: 4.0E + 10⁷, 2.0E + 10⁸) among visits where *Lactobacillus* was detected by culture. *L. crispatus* was detected by qPCR at 173 (46%) visits. Among visits with detectable *L. crispatus*, the median quantity was 5.6E + 10⁶ gene copies per sample (IQR: 7.0E + 10⁶, 4.1E + 10⁷). *L. jensenii* was detected slightly less often at 130 (35%) of visits. Among visits with detectable *L. jensenii*, the median quantity was 10.7E + 10⁶ gene copies per sample (IQR: 2.2E + 10⁶, 7.1 + 10⁶). *L. crispatus* alone was detected at 85 (23%) visits and *L. jensenii* alone was detected at 42 (11%) visits. Both bacteria were present at 88 (23%) visits and either *L. crispatus* and/or *L. jensenii* were present at 215 (57%) visits. Concordance between detection of *L. crispatus* and/or *L. jensenii* by qPCR and *Lactobacillus* by culture was 75% (kappa = 0.45), which equates to a modest level of agreement (Table 1).

Given the moderate level of agreement between culture and qPCR, we conducted an exploratory analysis using broad range PCR on a subset of culture samples that had high quantities of H₂O₂-producing *Lactobacillus* by culture, but were negative for both *L. crispatus* and *L. jensenii* in CVL by qPCR. Twenty-five samples from 13 different women met our inclusion criteria for the exploratory analysis (8 women had one sample, 4 women had 2 samples and 1 woman had 9 samples). We selected 16 samples to undergo additional broad range PCR testing: one sample from each participant with ≤2 eligible samples (n = 12) and 4 from the participant with 9 eligible samples. For participants with 2 eligible samples, the sample with the highest quantity of *Lactobacillus* by culture was selected. If the quantity of *Lactobacillus* by culture was the same, the first visit in the series was selected. For the participant with 9 eligible samples, the 4 with the highest quantities of *Lactobacillus* by culture were selected. The prevalence of *Lactobacillus* species detected by broad range PCR is presented in Table 2. *L. gasseri* was the dominant species and was present among 81% of samples, including all isolates from the participant who contributed 4 samples.

**Discussion**

Among HIV-1 seropositive women, 19% of samples with detectable *L. crispatus* or *L. jensenii* by qPCR were negative for H₂O₂-producing *Lactobacillus* by culture. It has been reported that 95% of *L. crispatus* isolates and 94% of *L. jensenii* isolates cultured from vaginal fluid were observed to be H₂O₂-producers [5]. The discordance observed in our initial analysis could be due to more frequent detection of H₂O₂-nonproducing strains of these species by qPCR, or the *L. crispatus* and *L. jensenii* strains that grow well in the laboratory may over-represent those that produce H₂O₂ compared to the original pool of bacteria. Conversely, a quarter of samples that were positive for H₂O₂-producing *Lactobacillus* by culture had undetectable quantities of *L. crispatus* and *L. jensenii* by qPCR. This finding may be due to the presence of other less prevalent *Lactobacillus* species such as *L. gasseri*, which is commonly an H₂O₂-producer [6]. This discordance prompted an exploratory analysis, which showed that *L. gasseri* was indeed the predominant

**Table 1 Lactobacillus species detected by qPCR compared to H₂O₂+ Lactobacillus detected by culture**

| Species Detected by PCR | H₂O₂+ Lactobacillus Detected by Culture |
|-------------------------|-----------------------------------------|

species detected among women who had high quantities of H$_2$O$_2$-producing Lactobacillus by culture ($\geq 10^6$ CFUs), but were negative for both L. crispatus and L. jensenii by qPCR. However, we did not develop or apply assays for every known Lactobacillus species. Note that we did not attempt to correlate culture results with detection of L. iners since this bacterium is typically not an H$_2$O$_2$ producer [5,16,23].

**Conclusions**

The two most prevalent H$_2$O$_2$-producing Lactobacillus species that colonize the vagina, L. crispatus and L. jensenii, were detected among three-quarters of specimens that had detectable H$_2$O$_2$-producing Lactobacillus by culture. However, one-quarter of specimens with detectable H$_2$O$_2$-producing Lactobacillus by culture were negative for L. crispatus and L. jensenii. This discordance lends support to the use of both culture and molecular methods to characterize the vaginal microbiota. Culture plays an important role in characterizing the vaginal microbiota, as they provide important phenotypic information. Compared to molecular methods, culture is inexpensive and requires less technical skill, time, and infrastructure to generate results. Information generated from the use of culture and molecular methods performed in combination will likely continue to generate useful information about how the vaginal microbiota impacts human health.

This analysis should be interpreted in the context of several limitations. Our analysis population consisted of HIV-1 seropositive women; therefore, our findings may not be generalizable to HIV-1 uninfected women. Since species level identification of Lactobacillus culture isolates was not performed, we can’t directly compare the species level concordance by culture and qPCR of CVL. We used species-specific qPCR assays that are highly sensitive and can detect species even at very low levels. However, we did not develop or apply assays for every known Lactobacillus species. Note that we did not attempt to correlate culture results with detection of L. iners since this bacterium is typically not an H$_2$O$_2$ producer [5,16,23].

## Table 2 Prevalence of Lactobacillus species detected using broad range PCR among a subset of culture samples*

| Species             | Number of samples with species detected$^3$ |
|---------------------|---------------------------------------------|
| n = 16              |                                             |
| L. gasseri          | 13 (81)                                     |
| L. crispatus        | 2 (13)                                      |
| L. iners$^2$        | 2 (13)                                      |
| L. johnsonii        | 2 (13)                                      |
| L. coleohominis     | 1 (6)                                       |
| L. oris             | 1 (6)                                       |
| L. reuteri          | 1 (6)                                       |
| L. rhamnosus        | 1 (6)                                       |

*Samples from women with high quantities of H$_2$O$_2$-producing Lactobacillus by culture ($\geq 10^6$ CFUs), but were negative for both L. crispatus and L. jensenii in CVL by qPCR.

$^1$Percent total $>100\%$ since several isolates contained more than one species.

$^2$H$_2$O$_2$-functionality was reassessed for the 2 isolates that were identified as L. iners. No H$_2$O$_2$-production was observed.

$^3$Samples from women with high quantities of H$_2$O$_2$-producing Lactobacillus by culture ($\geq 10^6$ CFUs), but were negative for both L. crispatus and L. jensenii in CVL by qPCR.

L. gasseri has been associated with the presence of abnormal vaginal microbiota [8], which may explain its detection in the absence of L. crispatus and L. jensenii, two species that are associated with a normal vaginal microbiota [4]. Though the proportion of L. gasseri isolates that are H$_2$O$_2$-producers is reported to be high (71-82%) [5,6], the prevalence of L. gasseri in the vagina is relatively low compared to L. crispatus and L. jensenii [5,16]. It is possible that L. gasseri is more prevalent in this population of HIV-1 infected women; however, since species-specific assays for L. gasseri were not performed and broad range PCR was conducted on only a subset of samples we do not know the overall prevalence of L. gasseri.

| Species             | Number of samples with species detected |
|---------------------|-----------------------------------------|
| n = 16              |                                         |
| L. gasseri          | 13 (81)                                 |
| L. crispatus        | 2 (13)                                  |
| L. iners$^2$        | 2 (13)                                  |
| L. johnsonii        | 2 (13)                                  |
| L. coleohominis     | 1 (6)                                   |
| L. oris             | 1 (6)                                   |
| L. reuteri          | 1 (6)                                   |
| L. rhamnosus        | 1 (6)                                   |

Our exploratory analysis also revealed a number of other Lactobacillus species besides L. crispatus, L. jensenii, and L. gasseri that appear capable of H$_2$O$_2$ production (Table 2). Among HIV-1 seropositive women, detection of H$_2$O$_2$-producing lactobacilli in the vagina has been associated with a reduced likelihood of genital HIV-1 shedding [2,3]. In addition, several epidemiologic studies conducted among HIV-seronegative women have reported an association between the presence of H$_2$O$_2$-producing Lactobacillus and a decreased risk of genital tract infections, including HIV-1 [17-20], leading to the hypothesis that H$_2$O$_2$ may inhibit genital tract pathogens. However, recent evidence indicates that in vivo concentrations of H$_2$O$_2$ produced from Lactobacillus may not be sufficient to provide protection against genital tract infections [21,22]. Given the evidence from epidemiological studies, it is possible that H$_2$O$_2$ production may serve as a marker for other phenotypes that play a role in the suppression of HIV-1 genital shedding and protection against genital tract infections. Additional studies are needed to improve our understanding of the biological mechanisms that contribute to reductions in genital HIV shedding and protection against genital tract infections.

Until recently, our understanding of the bacterial species associated with BV was limited to those species that could be detected by culture. Molecular techniques that detect bacterial genes such as the 16S ribosomal RNA (rRNA) gene have been used to characterize the vaginal microbiota and have revealed several new species [4]. Broad range and species-specific quantitative PCR assays allow for detection of both cultivation-resistant and cultivatable bacterial species, thus providing a more comprehensive characterization of the vaginal microbiota. However, cultivation approaches continue to play an important role in the characterization of the vaginal microbiota, as they provide important phenotypic information. Compared to molecular methods, culture is inexpensive and requires less technical skill, time, and infrastructure to generate results. Information generated from the use of culture and molecular methods performed in combination will likely continue to generate useful information about how the vaginal microbiota impacts human health.

This analysis should be interpreted in the context of several limitations. Our analysis population consisted of HIV-1 seropositive women; therefore, our findings may not be generalizable to HIV-1 uninfected women. Since species level identification of Lactobacillus culture isolates was not performed, we can’t directly compare the species level concordance by culture and qPCR of CVL. We used species-specific qPCR assays that are highly sensitive and can detect species even at very low levels. However, we did not develop or apply assays for every known Lactobacillus species. Note that we did not attempt to correlate culture results with detection of L. iners since this bacterium is typically not an H$_2$O$_2$ producer [5,16,23].
microbiota by determining the metabolic capabilities of these bacteria, while the use of molecular methods enables the detection of cultivable and cultivation-resistant species. The use of these methodologies in combination holds great promise for improving our understanding of the vaginal microbiota and the molecular epidemiology of BV.
