INTRODUCTION

Asymmetry in functional responses in the right and left hemispheres of a human brain has been observed (Toga and Thompson, 2003). Notable brain asymmetries include the dominance of the auditory cortex in the left hemisphere for speech processing (particularly, the left-side planum temporale region for consonant-vowel syllables, see Jancke et al. (2002), the theory of asymmetric sampling in time (Giraud et al., 2007), and that in the right hemisphere for music processing (Bever and Chiarello, 1974; Tervaniemi and Hugdahl, 2003). This asymmetric response is observed even in infants: speech (Dehaene-Lambertz et al., 2002) and music (Perani et al., 2010). However, Shtyrov et al. (1998) showed that, in a noisy environment, the involvement of the left auditory cortex in discriminating sounds considerably decreases, while that of the right hemisphere increases. This reveals that the existence of background noise in spoken words diminishes the dominant role of the left hemisphere in the speech processing (i.e., non-lateralization) (Wong et al., 2008).

Music processing is one of the most complex cognitive activities that the human brain performs. The detailed mechanism of music processing is not well understood yet. Even Bever and Chiarello (1974) had shown that the right lateralization in music processing is even higher among musicians than non-musicians, but still there are contradicting results among different genders, musicians, and non-musicians (Schuppert et al., 2000; Ono et al., 2011). To the best of our knowledge, the influence of background noise in music processing has not been fully investigated yet. The objectives of this study are first to investigate whether, in the presence of noise, the right-lateralization of music processing (in contrast to the speech processing) is destructed or not and second to characterize the noise levels in the music to any differences in the hemodynamic responses between the right and left auditory cortices.

In a live music environment, it will be interesting to categorize the level of noise that would not disturb the music. Under the assumption that the right-hemispheric lateralization exists (for some people), it will become the case that the introduced noise does not destroy the right lateralization in enjoying the music. Three distinguishing features of a sound are its intensity, frequency, and perception duration, which may elicit different responses to different humans. The study of audition (i.e., hearing a sound transmitted as acoustic waves) involves the examination of the sensory responses to the surrounding environment. To measure sensory responses, various modalities have been pursued in the past: For instance, electroencephalography (EEG) for detecting the language processing (Sinai and Pratt, 2003; Zaehle et al., 2007; Kuhnis et al., 2013b) and the music processing (Meyer et al., 2006; Headley and Pare, 2013) in the auditory cortex, and for detecting the P300 signals in the motor cortex (Turnip et al., 2011; Turnip and Hong, 2012; Khan et al., 2014; Soekadar et al., 2014) magnetoencephalography (MEG) for the auditory cortex (Shtyrov et al., 2012) and the motor cortex (Boulenger et al., 2012), functional magnetic resonance imaging (fMRI) for the auditory cortex (Warrier et al., 2009; Wong et al., 2010) and the...
fNIRS is a non-invasive method that measures the absorbed quantity of near-infrared light in the 650–950 nm wavelength range. fNIRS can detect the hemoglobin concentration changes in response to neural activities. For brain imaging, fNIRS offers higher temporal resolution than fMRI and higher spatial resolution than EEG. Particularly, while fNIRS can be used in a natural environment (particularly important in music processing), fMRI should be used in its designated place (or at least a simultaneous hearing and measurement cannot be done without an earphone). Recent fNIRS studies include the hemodynamics analyses in the prefrontal cortex (Hu et al., 2012; Naseer et al., 2013; Santosa et al., 2013; Bhutta et al., 2014), the motor cortex (Aqil et al., 2012a; Kamran and Hong, 2013, 2014), the visual cortex (Hong and Nguyen, 2014), the motor imagery (Naseer and Hong, 2013), and the somatosensory cortex (Hu et al., 2011). Particularly, fNIRS is suitable for studying the auditory cortex because of its non-invasiveness, mobility, cost, and most importantly silence of the equipment. On the other hand, fMRI is relatively problematic in studying the auditory cortex because its measurements are accompanied by acoustic noise resulting from slice selection pulses, cryogen pumping, and magnetic resonance gradient interference (Gaab et al., 2007). To solve the noise problem in fMRI, many schemes have been employed to shield the subject from the machine’s acoustic noise, although none of these methods have been proven effective: A few examples are sealing the gradient coil in a vacuum chamber (Katsunuma et al., 2002), using an active noise cancelation (McJury et al., 1997), and utilizing a low-noise gradient-coil design (Mansfield et al., 2001). The noise from an fMRI machine can even interfere with the stimuli designed to evoke neuronal activation: Fuchino et al. (2006) have shown that the level of oxy-hemoglobin in the sensorimotor cortex decreased with the increase of fMRI acoustic noise.

Conducting experiments using fNIRS, on the other hand, is much quieter than using an fMRI system, which makes fNIRS a much more suitable device for experiments related to audio stimulation. Another advantage of fNIRS is that it can detect two main chromophores: oxy-hemoglobin (HbO) and deoxy-hemoglobin (HbR), while fMRI can detect only the BOLD (blood oxygenation level dependent) signal (Plichta et al., 2006). When neuron fires, HbO decreases while HbR increases instantaneously (but it will bring more blood to the area, which will cause the increase of HbO). A drawback of fNIRS is the penetration depth of the light, which is limited to the cortical surface. However, even the relatively poor spatial resolution of fNIRS compared to fMRI (Kovelman et al., 2009) can be ignored due to its other strengths, the relatively faster time resolution than fMRI, low cost, portability, and quietness. While fNIRS enables testing under more relaxed conditions for the subjects, its results on the auditory cortex are relatively rare. The present study is to determine the effects of background noise in music processing: Fourteen healthy subjects participate, and the activations in the auditory cortices are recorded with fNIRS. Specifically, four different sound environments involving ten different conditions are designed for this experiment: music segments only, noise segments only, music segments including noise, and the entire music with noise segments. To investigate this, we examined the hemodynamic responses from 44 channels for three noise categories in both hemispheres.

Our interest exists in finding the (subjective) level of noise that does not disturb listening to music as well as hemispheric laterализation. The following questions will be pursued: (i) Are there more hemodynamic changes in the right auditory cortex than the left auditory cortex, when people hear music. Instead of listening to continuous music, music segments will be exposed to the subjects so that they can focus on. (ii) Can noise alone cause a similar behavior like music segments, or will it bring any difference? (iii) What would be the level of noise that distort the hearing status? (iv) What would be the noise enterance effects when listening to the entire music. As a feature to tell any difference, the gap between the mean value and the minimum value of the hemodynamic responses caused by various conditions will be used.

MATERIALS AND METHODS

SUBJECTS

Fourteen subjects (age: 28 ± 5 years; 7 males and 7 females, 12 right-handed and 2 left-handed) participated in the experiment, see ‘Table 1’. In this study, the handedness was obtained by asking the subjects about a better performance for use of a hand. Thirteen subjects knew (understood) the music and three subjects were musicians. The definition of musician in this work is whether they are able to play the music with piano or not. The response between musicians and non-musicians is known distinctly different (Kraus and Chandrasekaran, 2010; Kuhnis et al., 2013a, 2014). All musicians (1 male and 2 females; primary musical instrument: piano; mean age 25 ± 2 years) started their musical training between 6 and 12 years. They had more than 16 ± 2 years of musical training and practiced their musical instrument for 1.5 h/day when they started to learn piano. We selected the same number of subjects between male and female to examine a possible gender difference in the hemispheric laterализation (Shirao et al., 2005). All of them had normal hearing and none had a history of any neurological disorder. To reduce noise and artifacts, the subjects were asked to remain relaxed with closed eyes by enjoying the music and to avoid motions during the experiment (i.e., head movement, eye blinking, etc.). During the experiment, the subjects were asked to listen the auditory stimuli attentively (not passively), since selective attention is important to the activation pattern in the auditory cortex (Jancke et al., 1999). Moreover, musicians were asked to imagine playing the music with a piano. The work was approved by the Institutional Review Board of Pusan National University. The subjects were informed about the experimentation and written consents were obtained, which was conducted in accordance with the ethical standards encoded in the latest Declaration of Helsinki.

AUDIO STIMULI

Figure 1 shows the experimental paradigm used in this work. The audio stimuli (music) was Für Elise composed by Ludwig van Beethoven. The entire length of the music was 165 s. One
Table 1 | 14 Subjects in experiment.

| Subject | Gender | Age | -handed | (Pre-knowledge on the music) |
|---------|--------|-----|---------|-----------------------------|
| 1       | Male   | 29  | Left    | Yes                         |
| 2       | Male   | 27  | Left    | Yes                         |
| 3       | Male   | 34  | Right   | No                          |
| 4       | Male   | 29  | Right   | Yes                         |
| 5*      | Male   | 26  | Right   | Yes                         |
| 6       | Male   | 31  | Right   | Yes                         |
| 7       | Male   | 30  | Right   | Yes                         |
| 8       | Female | 26  | Right   | Yes                         |
| 9       | Female | 25  | Right   | Yes                         |
| 10      | Female | 23  | Right   | Yes                         |
| 11      | Female | 28  | Right   | Yes                         |
| 12*     | Female | 25  | Right   | Yes                         |
| 13*     | Female | 23  | Right   | Yes                         |
| 14      | Female | 26  | Right   | Yes                         |

*They can play the music.

The experiment consists of four stages involving ten conditions. The first 200 s after the pre-initiation trial constitutes Stage 1 (S1), which examines the basic condition (that is, a music hearing). In S1, the subjects are exposed to 25 s rest and 15 s music for 5 times (it is noted that the pre-initiation trial is not included in the analysis). The objective of S1 is to examine which side (right or left) in the brain is more active upon a musical stimulus. Stage 2 (S2) is the next 200 s after S1 that involves two different noise levels. Therefore, S2 constitutes three conditions: no noise (NN), mid-level noise (MN), and high-level noise (HN). The objective of S2 is to examine whether the noise can cause a similar response like the music in S1. Then, the subsequent 200 s after S2 becomes Stage 3 (S3), in which mixed music and noise segments are repeated 5 times. The objective of S3 is to find out whether a music + noise segment will induce more efforts in the brain than the cases of music or noise segments alone. Distinguishing NN, MN, and HN, 3 conditions are examined in S3. Finally, the interruption of noise when hearing the music has been mimicked in Stage 4 (S4). For comparison purposes, similar noise conditions like S2 and S3 are made in S4, yielding another 3 conditions. The noises introduced to the music appear in a pseudo-random order. The durations of music and noise segments in S1~S4 are the same. The shaded boxes in S3 and S4 indicate the time periods where noises enter the music. The total experimental time was 14 min and 50 s. The music and noises were digitally mixed using the Adobe Audition software (a WAV-format file: 16 bit, 44,100 Hz, stereo). The same earphone (Sony MDR-NC100D; digital noise canceling earbuds) with the same sound level setting was used across the subjects.

**Noise Levels**

The y-axis in Figure 1 denotes the relative amplitude of the audio signal (its max. scale has 30,000 sample values, which corresponds to 100%) in the Adobe Audition software. In this work, the high-level noise is defined to be the white noise whose amplitude reaches 20% of the full scale. The mid-level noise means 10% in the full scale. To provide variability, the noises were introduced in a pseudo-random order (15 s for each stimulus). The average amplitude of the music was about 10–15% in the y-axis.

**fNIRS DATA AND PROCESSING**

Figure 2 shows the optodes configuration of the fNIRS system (DYNOT: DYnamic Near-infrared Optical Tomography; NIRx Medical Technologies, Brooklyn, NY) for imaging the auditory cortices in the left and right hemispheres. The distance between an emitter and a detector is 23 mm. The data were acquired at a sampling rate of 1.81 Hz and for two wavelengths (760 and 830 nm). A total of 22 channels were measured from 8 emitters (black circles) and 7 detectors (white circles) in both hemispheres. All the lights in the room were turned off during the experiment to minimize signal contamination from the ambient light sources. The optodes were placed on the scalp above the left and right auditory cortices. Ch. 16 in both left/right hemispheres was set to coincide with the T3/T4 locations, respectively, in the International 10–20 system. Since the optodes configuration in Figure 2 covers the entire auditory cortex, the averaged value from the 22 channels is used in the analysis.

Relative changes of the concentrations of HbO and HbR were computed using the modified Beer-Lambert Law as follows,

\[
\Delta A_i(\lambda, k) = \left[ a^{\text{HbO}}(\lambda) \Delta c^{\text{HbO}}(k) + a^{\text{HbR}}(\lambda) \Delta c^{\text{HbR}}(k) \right] d_i, \tag{1}
\]

where \( \Delta A \), \( k \) is the absorbance variation at time \( k \); the subscript \( i \) denotes the channel number; \( \lambda \) is the wavelength of the laser source; \( a^{\text{HbO}} \) and \( a^{\text{HbR}} \) are the absorption coefficients of HbO and HbR, respectively; \( \Delta c^{\text{HbO}} \) and \( \Delta c^{\text{HbR}} \) are the concentration changes of HbO and HbR, respectively; and \( d \) is the differential path length factor (in this study, constant values \( d = 7.15 \) for \( \lambda = 760 \text{ nm} \) and \( d = 5.98 \) for \( \lambda = 830 \text{ nm} \) were used for all the channels), and \( i \) is the distance between a source and a detector.

To analyse the fNIRS data, the open-source software NIRS-SPM (Ye et al., 2009) was utilized in our own Matlab® (Mathworks, Natick, MA) code. The respiration and cardiac noises contained in the hemodynamic responses were removed by a low-pass filter of a cut-off frequency 0.15 Hz.

**Classification Feature**

The difference between the mean and the minimum value of a given hemodynamic response has been used as a feature to classify whether the hemispheric lateralization occurred or not. Figure 3 depicts a typical activated hemodynamic response obtained by convolving a stimulus pattern and the impulse hemodynamic response function as

\[
h_M(k) = \sum_{n=-\infty}^{\infty} \text{Box}(k) h(k - n), \tag{2}
\]

where \( h_M(k) \) denotes the “modeled” hemodynamic response to be used as a reference signal, \( \text{Box}(k) \) is the box-type stimulus pattern (in this paper, the 15 s activation period) and \( h(k) \) is the impulse hemodynamic response function adopted from the SPM8 (Wellcome Trust Centre for Neuroimaging, London, UK)
Santosa et al. Lateralization of music processing

FIGURE 1 | Experimental paradigm. Four different sound conditions. The level of noise (i.e., NN, no noise; MN, mid-level noise; HN, high-level noise) changes in a pseudo-random order.

(Friston et al., 2008). For example, the curve in Figure 3 shows that the mean value is 0.36 μM, the minimum value is -0.12 μM, and therefore the difference is 0.48 μM. The reason for using the gap between the mean and the minimum value of the hemodynamic response as a classification index in this work is that, with the current experimental paradigm in Figure 1, the hemodynamic response may not come back to the baseline value in a short time interval after each stimulus. Actually, it was so and the baseline drifting has been compensated by the mean-min difference.

STATISTICAL ANALYSIS

The estimation of the cortical activation is the most important factor in the analysis of fNIRS data. Previous studies showed that the activation could be statistically estimated by fitting the measured response to a regression model (Hu et al., 2010; Aqil et al., 2012b). Let \( h_j^i \in R^{N \times 1} \) be the measured fNIRS data at the \( i \)-th channel, the superscript \( j \) denote the \( j \)-th stimulus (i.e., the total 20 stimuli obtained by 5 stimuli/condition × 4 conditions), and \( N \) be the size of fNIRS data for each stimulus (in this study, \( N = 72 \) for the period of 15 s stimulus and 25 s rest using the sampling frequency of 1.81 Hz). Then, the general linear regression model is formulated as follows,

\[
\begin{align*}
\text{h}_j^i = & \phi_j^i \text{h}_M^i + \psi_j^i \cdot 1 + \varepsilon_j^i, \\
\end{align*}
\]

where \( \text{h}_M^i \in R^{N \times 1} \) is the modeled hemodynamic response obtained by (2), \( 1 \in R^{N \times 1} \) is a column vector of ones for correcting the baseline, \( \phi \) is the unknown coefficient that indicates the activity strength of the modeled hemodynamic response, \( \psi \) is the coefficient to compensate the baseline drift of the signal, and \( \varepsilon \in R^{N \times 1} \) is the error term in the regression model. In this paper, the coefficient \( \phi \) is estimated by using the robustfit function available in Matlab™ as follows,

\[
\begin{pmatrix}
\hat{\phi}_j^i \\
\hat{\psi}_j^i
\end{pmatrix}, \text{stats} = \text{robustfit}([1 \text{ h}_M], \text{h}_j^i),
\]

Frontiers in Behavioral Neuroscience www.frontiersin.org December 2014 | Volume 8 | Article 418 | 4
\[ \hat{\phi}_j^i \text{ and } \hat{\psi}_j^i \text{ denote the estimate of } \phi_j^i \text{ and } \psi_j^i, \text{ respectively, and } \text{Stats} \text{ denotes the statistical data including the } t\text{-value, } p\text{-value, standard errors, etc.} \]

The idea is to test the null hypothesis that the estimated parameter \( \hat{\phi}_j^i \) is equal to zero or not. Furthermore, if \( \hat{\phi}_j^i \) is positive, the particular activation is assumed to be active, and if it is negative, the particular activation is not active for the \( j \)-the stimulus at the \( i \)-th channel, in which the \( t \)-value test has been used. In this paper, the \( t \)-value was computed using the following equation,

\[ t_j^i = \frac{\hat{\phi}_j^i}{SE(\hat{\phi}_j^i)}, \tag{5} \]

where \( SE \) is the standard error of the estimated coefficient. We used two criteria to assess the selection reliability of a particular activation for further analysis. They were \( t_j^i > 0 \) and \( p_j^i < \alpha \), where \( \alpha \) denotes the \( p \)-value (in this work, \( \alpha = 0.05 \) was set).

Alternatively, it could be done by checking \( t_j^i > t_{\text{crit}} \), where \( t_{\text{crit}} \) denotes the critical \( t \)-value that depends on the degree of freedom (i.e., 71, which is \( N-1 \)). In this case, \( t_{\text{crit}} = 1.994 \).

where \( \hat{\phi}_j^i \) and \( \hat{\psi}_j^i \) denote the estimate of \( \phi_j^i \) and \( \psi_j^i \), respectively, and \( \text{Stats} \) denotes the statistical data including the \( t \)-value, \( p \)-value, standard errors, etc.

The idea is to test the null hypothesis that the estimated parameter \( \hat{\phi}_j^i \) is equal to zero or not. Furthermore, if \( \hat{\phi}_j^i \) is positive, the particular activation is assumed to be active, and if it is negative, the particular activation is not active for the \( j \)-the stimulus at the \( i \)-th channel, in which the \( t \)-value test has been used. In this paper, the \( t \)-value was computed using the following equation,

\[ t_j^i = \frac{\hat{\phi}_j^i}{SE(\hat{\phi}_j^i)}, \tag{5} \]

where \( SE \) is the standard error of the estimated coefficient. We used two criteria to assess the selection reliability of a particular activation for further analysis. They were \( t_j^i > 0 \) and \( p_j^i < \alpha \), where \( \alpha \) denotes the \( p \)-value (in this work, \( \alpha = 0.05 \) was set).

Alternatively, it could be done by checking \( t_j^i > t_{\text{crit}} \), where \( t_{\text{crit}} \) denotes the critical \( t \)-value that depends on the degree of freedom (i.e., 71, which is \( N-1 \)). In this case, \( t_{\text{crit}} = 1.994 \).

RESULTS

The hemodynamics changes in the auditory cortex upon the occurrence of noises in music processing have been examined. Using the paradigm in Figure 1, four different stages involving ten conditions in combination with three different noise levels were tested. The three-digit numbers in Table 2 indicate the differences between the mean and the minimum value of the HbO concentration change in both left and right auditory cortices for 14 subjects (Subject 1~14). S1~S4 represent four different experimental stages in Figure 1. It is reminded that only those hemodynamic responses whose \( p < 0.05 \) and \( t > 0 \) were counted for averaging over 22 channels. It is also noted that (i) the data outside the 3 standard deviations were excluded (i.e., 9 cases in bold-italic in Table 2 were outliers, see Subject 5 and Subject 12) and (ii) if a right-left difference is not significant (i.e., difference < 0.1\sigma), it was considered to be the same (they were marked in italic font). Table 3 summarizes Table 2. The following observations are made:

i) Music segments stage (S1): This stage was to determine which brain side was dominant in music processing. Nine subjects showed the higher activation in the right auditory cortex, whereas three subjects showed it in the left auditory cortex (out of 14 subjects, Subject 12 was an outlier and the data of Subject 10 was undistinguishable). Therefore, the right-hemispheric lateralization in music processing is about 75\% (i.e., 9/12).

ii) Noise segments stage (S2): This stage intended to characterize the auditory responses to various noises. When there was no noise (see the first row in S2), a significant difference was not seen between the right and left auditory cortices, considering that two data (Subject 10, Subject 14) were indistinguishable and one data (Subject 12) was an outlier. But, in the mid- and high-noise conditions, there was a slight increase in the number of subjects who showed the higher hemodynamics response in the right auditory cortex (i.e., 15/23, which is about 65\%).

iii) Mixed music and noise stage (S3): Contrary to S1 (music only) and S2 (noise only), mixed signals of noise and music
were exposed to the subjects. Considering that the sound level of the music was about 10−15%, the mid-level noise and music segments showed the highest level of right-lateralization over the subjects (see the second row in S3). Actually, removing two undistinguishable subjects (Subject 11, Subject 14), all twelve subjects out of 14 subjects showed the higher activation in the right auditory cortex. This is due to that the subjects tried to hear the music in the presence of noise (recall that the noise level was 10%). But, if the noise level became higher than the sound level of music (i.e., the high-noise condition, 20%), the number of subjects who showed the higher activation in the right auditory cortex had reduced to 10. Another interesting observation was found from the first row in S3, which provided no sound in the middle of music + noise segments. No sound itself had shown almost the same level of right-lateralization in terms of number of subjects as the case of music + high-noise condition.

iv) The entire music with noise segments (S4): The final stage was to investigate the effect of noise interruptions in hearing music. When there was no noise (see the first row in S4), the tendency of the right-hemispheric lateralization was exactly the same as the case of S1 (i.e., 75%). Also, even upon the interruptions of noise, the tendency was similar.

For the 140 cases (i.e., 14 subjects × 10 conditions), 9 cases were outliers, 11 cases showed no significant difference, 32 cases showed the higher left auditory cortex, and finally 88 cases showed the higher right auditory cortex. Therefore, the overall lateralization across all the experimental conditions was about 73.3% (i.e., 88/120); specifically, for female 81.1% (i.e., 43/53) and for male 67.2% (i.e., 45/67). It is also noted that 20 cases were excluded.

Now, for analyzing the tendency/strength of lateralization, only the cases showing that the right hemisphere is more active than the left hemisphere were further considered (bold font). Table 4 shows the average and its standard deviation of such cases. That is, the value 2.080 in S1 is the average of 1.453, 2.596, 2.458, 1.704, 2.494, 2.394, 2.357, 2.013, and 1.253 from Table 2. The following observations are made. (i) Comparing S1 and S4 in Table 4, the background noise intensifies the hemispheric lateralization (i.e., the Right Avg—Left Avg value has increased from 0.311 for music only condition to 0.533 for the mid-noise condition and 0.743 for the high-noise condition, respectively). (ii) As seen in the last column of S2, the difference in the mid-noise condition (i.e., 0.536) is larger than the other two cases (i.e., 0.315 and 0.403). This may reveal the fact that too much noise does destroy the subject’s discerning efforts for music in the presence of noise. (iii) In S3, even if there is no sound, the difference in the right auditory cortex was higher than that of the left (i.e., 0.566). This reflects that, in the presence of noise, the subjects tried to listen to the music and this effort was continued even if there is no sound. A similar effort from the subjects was also shown in the mid- and high-noise conditions. Overall, the discerning efforts for music from noises has been seen, which is consistent throughout all three conditions.

### Table 4: Differences between the mean and the minimum value of the H2O concentration (unit: M, scale-up by 10^-4).

| Condition | Subject 1     | Subject 2     | Subject 3     | Subject 4     | Subject 5     | Subject 6     | Subject 7     | Subject 8     | Subject 9     | Subject 10    | Subject 11    | Subject 12    |
|-----------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|

Subs. 1−7 are males and 8−14 are females. Bold-face numbers indicate that the mean-min difference in the right hemisphere is larger than that in the left hemisphere.
The previous MEG data on speech stimuli (Shtyrov et al., 1998), showed that lateralization occurs in the right hemisphere. This result, in fact, is in line with previous studies showing that the specialized function of the brain. Similar results from the previous studies on speech stimuli show that lateralization occurs in different responses for noisy condition.

fNIRS have its advantages over fMRI. Previous studies have employed fMRI to determine the effects of various stimuli on neuronal activation in the auditory cortex (Scarff et al., 2004). The drawback of this modality is the problematic effect of acoustic noise from baseline activity in the auditory cortex. Whereas fMRI can measure the changes in magnetic susceptibility in the blood, fNIRS can directly measure hemodynamic changes, HbO and HbR. fMRI signals are physiologically ambiguous, because they reflect changes in cerebral blood flow, cerebral blood volume, and oxidative metabolism. Many studies have investigated the correlation between fMRI and fNIRS signals (Yuan and Ye, 2013). By contrast, the present study focused on the Hbo values, as they offer results that are more direct than HbR (Plichta et al., 2006).

We employed the fNIRS technique directly because of its inherent advantages in the analyses of sound-evoked activation: indeed, as a brain-imaging tool, it works non-invasive and silent. Lateralization means a more blood flow in one hemisphere in fNIRS. With this, we assume that more neuronal activity has been made in that region (but, this might be caused by different capillaries in that region or from other aspect, which deserves further neurophysiological investigation). We obtained all of the music stimuli results by examining the gap between the mean value and the minimum value of the Hbo taken from individual channels covering the auditory cortex. This study observed a pattern of Hbo activation that supports the view of functional lateralization in the auditory cortex. Since a variety of light penetrates through the scalp, we can get reliable experimental results by using the difference between the mean and the minimum value of the Hbo with two criteria (t and p values) for statistical analyses. A possible explanation for the difference between S3 and S4 could be due to the influence of emotional behavior on the classical music. Music may contain features that evoke positive (or negative) emotional responses. Hemispheric lateralization increases when noise appeared in S4, which was different from S3.

Another possible explanation for the differences between the results of S3 and S4 could be the full-length music played in the background while introducing the different level of noise. Für Elise composed by Ludwig van Beethoven is a commonly known music that everyone can recognize and possibly imagine. Prior research has shown that music perception and music imagination has similarities in brain activation and neural mechanism (Zatorre et al., 1996). If a continuous music was cut off due to noise for a short period of time, the noise level should not make a difference if the subject can imagine the missing portion of the music. These findings further support the idea of the specialization in the auditory cortex evoked by audio stimuli.

**DISCUSSION**

This was the first fNIRS study to examine whether auditory-cortex activation by background-noise and music stimuli could change the hemispheric lateralization in both hemispheres. To investigate the effects of noise on music processing, the participants were subjected to various levels of noises in different conditions in the experiment. It was found that exposure to any noise compared to no noise led to higher auditory-cortex activation in the right hemisphere. This result, in fact, is in line with the previous MEG data on speech stimuli (Shtyrov et al., 1998), wherein instead the left hemisphere was dominant in the perception and production of speech. However, when high-level noise was introduced, activation was observed in both hemispheres resulting in a lack of lateralization in auditory-cortex activation. This clearly demonstrates that auditory-cortex activation by music stimuli with noise changes the hemispheric lateralization when a sufficiently loud distraction is introduced to reduce the specialized function of the brain.

**CONCLUSIONS**

The main finding of this study was that background noise affects the hemodynamic response in the activation of the auditory cortex in music processing. Under various noise levels throughout the four different stages involving ten conditions of the
experiment, the involvement of the right hemisphere's auditory cortex was higher than that of the left hemisphere (overall 73.3%, specifically, 67.1% for male and 81.1% for female). Particularly, the subjects listened to the music segments, the lateralization was 75%. Also, if only noise segments were heard, the lateralization was about 65%. But if the music was mixed with noise, such lateralization tendency became intensified. Particularly, the music + noise segments condition revealed 100% right-lateralization when the music level was 10~15% and the noise level was 10%. However, the noise level became too big (i.e., noise 20%, music 10%), the lateralization had reduced. This is an indication that too much noise diminishes the human's efforts to discern the music from surrounding noises. The obtained results support the theory that the brain is divided into compartments specializing in specific functions.

**AUTHOR CONTRIBUTIONS**

Hendrik Santos performed the experiment and carried out the data processing, Melissa Jiyoun Hong provided suggestions to improve the manuscript, and Keum-Shik Hong supervised the research and corrected the entire manuscript. All of the authors read and approved the final manuscript.

**ACKNOWLEDGMENTS**

This work was supported by the National Research Foundation of Korea (grant no. NRF-2012-R1A2A2A01046411 and NRF-2014-R1A2A1A10049727).
