\section*{ABSTRACT}
At redshift $z \gtrsim 5$ Type II supernovae (SNII) are the only known dust sources with evolutionary timescales shorter than the Hubble time. We extend the model of dust formation in the ejecta of SNII by Todini \& Ferrara (2001) to investigate the same process in pair-instability supernovae (PISN), which are though to arise from the explosion of the first, metal free, very massive ($140-260 M_\odot$) cosmic stars.

We find that 15\%-30\% of the PISN progenitor mass is converted into dust, a value > 10 times higher than for SNII; PISN dust depletion factors (fraction of produced metals locked into dust grains) range between 0.3 and 0.7. These conclusions depend very weakly on the mass of the PISN stellar progenitor, which instead affects considerably the composition and size distribution. For the assumed temperature evolution, grain condensation starts 150-200 days after the explosion; the dominant compounds for all progenitor masses are SiO$_2$ and Mg$_2$SiO$_4$ while the contribution of amorphous carbon and magnetite grains grows with progenitor mass; typical grain sizes range between $10^{-3}$ and a few 0.1$\mu$m and are always smaller than 1$\mu$m.

We give a brief discussion of the implications of dust formation for the IMF evolution of the first stars, cosmic reionization and the intergalactic medium.

\textbf{Key words:} galaxies: formation - first stars - supernovae:general - dust - cosmology: theory

\section*{1 INTRODUCTION}
In the recent years, dust has been recognized to have an increasingly important role in our understanding of the near and distant Universe. The dramatic effect of dust at low and moderate redshifts has been immediately recognized when a reconstruction of the cosmic star formation history from rest-frame UV/visible emission was first attempted: dust grains absorb stellar light and re-emit it in the FIR. Thus, even a tiny amount of dust extinction can lead to a severe underestimate of the actual star formation rate (Pettini \textit{et al.} 1998; Steidel \textit{et al.} 1999). New IR, FIR and submm facilities have revealed the existence of populations of sources, such as SCUBA $z \gtrsim 1$ sources, that are thought to be dust-enshrouded star forming galaxies or AGNs (Smail \textit{et al.} 1997; Hughes \textit{et al.} 1998) or the Extremely Red Objects, which are at least partly populated by dusty star-forming systems at $z \sim 1$ (Cimatti \textit{et al.} 2002). Finally, dust plays a critical role in galaxy evolution, accelerating the formation of molecular hydrogen (H$_2$), dominating the heating of gas through emission of photoelectrons in regions where UV fields are present and contributing to gas cooling through IR emission (see Draine 2003 for a recent thorough review).

These observational evidences have motivated a series of studies aimed at including a treatment of dust formation within galaxy evolution models (Granato \textit{et al.} 2000; Hirashita \& Ferrara 2002; Morgan \& Edmunds 2003). Since dust formation in the interstellar medium (ISM) is extremely inefficient (Tielens 1998), the preferential sites of formation are considered to be the atmospheres of evolved low-mass ($M < 8 M_\odot$) stars, from where it is transported into the ISM through stellar winds (Whittet 1992). However, this mechanism can not explain the presence of dust at redshifts $> 5$ because at these high redshifts the evolutionary timescales of low-mass stars (0.1 – 1 Gyr) start to be comparable with the age of the Universe.

Evidences for the presence of dust at high redshifts come from observations of damped Ly\alpha systems (Pettini \textit{et al.} 1994; Prochaska \& Wolfe 2002; Ledoux, Bergeron \& Petitjean 2002) and from the detection of dust thermal emission from high redshift QSOs selected from the SDSS survey out to redshift 5.5 and re-observed at mm wavelengths (Omont \textit{et al.} 2001; Carilli \textit{et al.} 2001; Bertoldi \& Cox 2002). Very recently, Bertoldi \textit{et al.} (2003) have reported the observations of three $z > 6$ SDSS QSOs at 1.2 mm, detecting thermal dust radiation. From the IR luminosities, the estimated dust masses are huge (> $10^8 M_\odot$) implying a high abundance of heavy elements and dust at redshifts as high
as 6.4 that can not be accounted by low-mass stars. Thus, dust enrichment must have occurred primarily on considerably shorter timescales in the ejecta of supernova explosions (Dwek & Scalo 1980; Kozasa, Hasegawa & Nomoto 1989; Todini & Ferrara 2001; Nozawa et al. 2003).

The strongest evidence for dust formation in supernova explosions was seen in SN 1987A (Moseley et al. 1989; Wooden 1997). In this event, the increased IR emission was accompanied by a corresponding decrease in the optical emission and the emission-line profiles were observed to shift toward the blue (McCray 1993 and references therein). In another supernova explosion, SN 1998S, the observed evolution of the hydrogen and helium line profiles argues in favor of dust formation within the ejecta as the redshifted side of the profile steadily faded while the blueshifted side remained constant (Gerardy et al. 2000). Dust emission has been seen in the supernova remnant Cassiopeia A: similarly to SN 1987A, the total dust mass derived from IR luminosities is less than expected from theory, suggesting that a colder population of dust grains may be present that emit at longer wavelengths and it is not detectable in the IR (Morgan & Edmunds 2003; Dunne et al. 2003). Finally, in a considerable number of cases, supernovae have shown IR emission that was stronger toward longer wavelengths (see Gerardy et al. 2002 and references therein). This IR excess has been generally interpreted as due to thermal emission from dust forming in the ejecta but alternative explanations exist; in particular, new IR observations of five Type II SNe have shown late-time emission that remains bright many years after the maximum and that it is hard to reconcile with emission from newly formed dust; IR echos from pre-existing dust in the circumstellar medium heated by the supernova flash might represent an alternative interpretation (Gerardy et al. 2002).

Theoretical studies have started to investigate the process of dust formation in expanding SN ejecta. Most of the available models are based on classical nucleation theory and grain growth (Kozasa & Hasegawa 1987; Todini & Ferrara 2001) with the exception of the computations recently performed by Nozawa et al. 2003, who have made an extensive analysis of dust grain properties forming in zero-metallicity SNe of various masses. The model developed by Todini & Ferrara (2001) is able to predict the dust mass and properties as a function of the initial stellar progenitor mass and metallicity. In spite of the many uncertainties and approximations, this model has been shown to satisfactorily reproduce the observed properties of SN 1987A and of the young dwarf galaxy SBS 0335-052 (Hirashita, Hunt & Ferrara 2002).

In this paper, we investigate the formation of dust grains in the ejecta of very massive primordial supernovae, which are commonly known as pair-creation or pair instability SNe (PISN). These violent explosions are thought to terminate the life of metal-free stars with initial mass in the range $140 M_\odot \leq M \leq 260 M_\odot$ (Heger & Woosley 2002). Indeed, detailed theoretical modelling of the nucleosynthesis and internal structure of these very massive stars has shown that after central helium burning electron/positron pairs are created, converting a large fraction of internal energy into rest mass of the pairs; as a consequence, the stars rapidly contract until explosive oxygen and silicon burning is able to revert the collapse and the stars are completely disrupted in giant explosions (Fryer, Woosley & Heger 2001). Below and above the mass range of PISN, the most likely outcome of the evolution of metal-free stars appears to be black hole formation, cleanly separating the contribution to metal and eventually dust production of such very massive stars from that of other mass ranges.

We base our analysis on the model developed by Todini & Ferrara (2001) and apply it to PISN. We therefore change the initial chemical composition of the ejecta and also the thermodynamical/dynamical properties which determine the ejecta evolution. A larger amount of dust is expected to form in the ejecta of PISN with respect to Type II SNe, because of the larger amount of metals released and the absence of fallback of material onto the compact remnant (no remnant is expected to survive PISN explosions).

The motivation for the present study comes from the increasing number of evidences which seem to indicate that the first stars that were able to form in the early Universe from the collapse of metal-free gas clouds were indeed very massive, with characteristic masses of a few 100 $M_\odot$. These include detailed numerical simulations (Abel, Bryan & Norman 2000, 2002; Bromm, Coppi & Larson 1999, 2002; Bromm et al. 2001; Coriano et al. 2002). semi-analytic models (Omukai & Nishi 1998; Nakamura & Umemura 2001, 2002; Schneider et al. 2002) and several pieces of observations (Hernandez & Ferrara 2001; Oh et al. 2001; Salvaterra & Ferrara 2002; Schneider et al. 2003). In particular, some of these studies have pointed out that because of the reduced cooling gas efficiency, low-mass star formation is strongly inhibited before a minimum level of metal enrichment of the collapsing gas cloud has been reached (Bromm et al. 2001, Schneider et al. 2002). The value of this minimum level, $Z_{\text{cr}}$ is very uncertain, but likely to be between $10^{-6}$ and $10^{-4} Z_\odot$ (Schneider et al. 2002; 2004). Within this critical range of metallicities, the presence of dust appears to have a major role, providing an additional pathway for cooling the gas, that fragments into lower mass clumps enabling the formation of second-generation low-mass stars (Schneider et al. 2003). Thus, to estimate the efficiency of this dust-regulated low-mass star formation channel in very metal-poor gas clouds, it is crucial to develop a model which is able to predict the amount of dust formed in the ejecta of PISN.

## 2 DUST FORMATION MODEL

The process of dust formation and the resulting dust grain properties depend on the physical conditions at the site of formation. In particular, several studies (see Kozasa, Hasegawa & Nomoto 1989 and references therein) have shown that the time of onset of grain formation depends on the temperature structure in the supernova ejecta whereas the grain composition mainly reflects its chemical composition, which depends on the nucleosynthesis occurring during stellar lifetime (i.e. on the progenitor mass) and explosion.

Thus, models of dust formation in supernova ejecta are based on specific prescriptions for the chemical composition and thermodynamics of the expanding gas. At the onset of shock generation, which occurs at the boundary of the innermost Fe-Ni core, the progenitor star is characterized by the standard stratified (onion-skin) structure. During shock
propagation through the star, the gas undergoes a new phase of (explosive) nucleosynthesis and mixing of the internal layers is thought to occur at least up to the outer edge of the helium layer, as suggested by observations of early emergence of $\gamma$ and X-rays in SN 1987A (Kumagai et al. 1988 and references therein). These observations confirm that macroscopic mixing of the ejecta occurs through Rayleigh–Taylor instabilities but it is still very debated whether mixing is extended at molecular level (Clayton et al. 1999; 2001).

The model of Todini & Ferrara (2001) (but see also Kozasa et al. 1989) is based on the assumption that materials are uniformly mixed from the center to the helium outer edge. As a consequence, the temperature and density within this metal-rich volume are assumed to be constant. When the shock reaches the surface of the progenitor, the star starts to expand and the expansion becomes homologous. Thus, the velocity of gas at a given layer is constant in time and proportional to the radius from the center, i.e. $v = R/t$, where $t$ is the time from the explosion and the expansion velocity is assumed to be

$$v = \left( \frac{E_{\text{kin}}}{M_{\text{tot}}} \right)^{1/2}$$

where $E_{\text{kin}}$ and $M_{\text{tot}}$ are the kinetic energy and total mass ejected by the supernova. The temperature of the expanding ejecta is determined by various heating and cooling mechanisms. Todini & Ferrara (2001) following Kozasa et al. (1989) assumed that when the gas reaches the photosphere, the gas temperature is equal to the photospheric temperature and thereafter the temperature evolution follows from the assumptions of adiabatic expansion for a perfect-gas, so that

$$T = T_i \left( 1 + \frac{v}{R_i} t \right)^{(3(1-\gamma))}.$$

where $\gamma$ is the adiabatic index and the quantities $T_i$ and $R_i$ are the photospheric temperature and radius obtained from the observational results of SN 1987A (Catchpole et al. 1987). The lack of observational constraints for PISN forces us to model the thermal evolution of the expanding ejecta on the basis of theoretical considerations. In particular, the evolution and internal structure of PISN have been studied in great detail through numerical simulations (Fryer, Woosley & Heger 2001; Heger & Woosley 2002). Zero-metallicity progenitor stars with masses between 140 $M_\odot$ and 260$M_\odot$ evolve without significant mass loss until central helium burning. These stars, after central helium depletion, have enough central entropy that they enter a temperature and density regime in which electron/positron pairs are created in abundance, converting internal gas energy into rest mass of the pairs, without contributing much to the pressure. When this instability is encountered, the stars contract rapidly until explosive oxygen and silicon burning produce enough energy to revert the collapse and the stars are completely disrupted in a giant explosion. The maximum central temperature and density during the bounce as a function of the PISN progenitor mass together with the elemental composition of the emerging ejecta are shown in Fig. 1. The dominant metal yields show that nucleosynthesis in pair-creation supernovae produce a total mass of O, Si, Mg and Al which is roughly independent of the initial progenitor mass but an Fe mass which varies greatly with the mass of the progenitor, being almost negligible for initial stellar masses $< 200M_\odot$. It is important to stress that this should be interpreted as the iron mass only after all unstable isotopes have decayed. Indeed, unlike Type II SN progenitors, PISN progenitors do not build up an iron core before the explosion and the final Fe mass is generated through the decay of $^{56}$Co. We will consider this process in detail as this decay provides the relevant destruction process of CO molecules.

The internal structure of the star at this maximum central density appears to have an approximately constant density, $\rho_c$, and temperature, $T_c$, up to the outer edge of the helium core (Fryer et al. 2001). We can adopt these values as the initial density and temperature of the volume where the metals are uniformly mixed at shock generation. Indeed, the time it takes the shocks to propagate through the low-density hydrogen envelope and reach the surface of the progenitor, starting the stellar expansion, is negligible. Adopting this normalization in Eq. 2, we can follow the evolution of the supernova ejecta. The results are shown in Fig. 2. In the top and medium panels we show the evolution of radius and number density of the ejecta of a 195 $M_\odot$ pair-creation supernova as a function of the time elapsed from the explosion. In the bottom panel, we show the corresponding evolution of the temperature. Two different regimes can be identified: in the initial phase of the evolution, the ejecta is radiation-dominated and we assume an adiabatic index $\gamma = 4/3$. This appears to be consistent with the internal

**Figure 1.** *Top panel:* dominant metal yields [$M_{\text{Fe}}$] of PISN (Heger & Woosley 2002) as a function of the progenitor stellar mass, after all unstable isotopes have decayed. *Bottom panel:* kinetic energy (in units $10^{51}$ erg), velocity of the ejecta (in units $10^3$ km/s), central temperature (in units $10^9$ K) and density (in units $10^9$ gr/cm$^3$) as a function of the progenitor stellar mass (see text).
Figure 2. Dynamics and thermodynamics of the ejecta for a 195 $M_\odot$ PISN. The top, medium and bottom panels show the time evolution of the radius, Log [R/km], number density, Log [n/cm$^3$], and temperature, Log [T/K], of the expanding gas. The temperatures corresponding to the onset of grain condensation ($T \leq 2000$ K) and to the final state followed by the model ($T = 500$ K) are indicated with two horizontal lines.

structure of the 250 $M_\odot$ star at maximum central density in the simulation of Fryer et al. (2001), which shows a density and temperature profile in the outer H-envelope compatible with $\gamma \simeq 4/3$. However, for $t > 111.26$ days (where 111.26 days is $^{56}$Co e-folding time) energy deposition from decaying radioactive elements is negligible and the gas cools adiabatically with $\gamma = 5/3$. A comparable thermal history is found by Nozawa et al. (2003) solving the radiative transfer equation and taking into account the energy deposition by radioactive elements. For the same PISN progenitor mass, however, their normalization is slightly higher (by a factor $\sim 3$) because of the different input stellar models (Umeda & Nomoto 2002).

3 MODEL RESULTS

In the model of Todini & Ferrara (2001), the formation of dust grains from a gaseous metal-rich medium is described as a two step process: (i) the formation of “critical clusters” at the corresponding condensation barrier and (ii) the subsequent growth of these clusters into macroscopic dust grains through mass accretion. A thorough description of the model, which follows the classic theory of nucleation, can be found in the paper of Todini & Ferrara (2001) to which we refer interested readers.

In the present study, we follow the formation of seven solid compounds, namely, $\text{Al}_2\text{O}_3$ (corundum), iron, $\text{Fe}_3\text{O}_4$ (magnetite), $\text{MgSiO}_3$ (enstatite), $\text{Mg}_2\text{SiO}_4$ (forsterite), $\text{SiO}_2$ and amorphous carbon (AC) grains. The corresponding chemical reactions are listed in Table 1. Numerical constants can be found in Table 1 of Todini & Ferrara (2001) except for $\text{SiO}_2$, for whom we have adopted the values used by Nozawa et al. (2003).

It is important to note that, as we will see, AC grains can form also if the ejecta composition is richer in oxygen than in carbon (O > C) as Clayton, Liu & Dalgarno (1999) have shown. The formation of CO and SiO molecules in SN ejecta can be very important for dust formation, because carbon atoms bound in CO molecules are not available to form AC grains and SiO molecules take part in the reactions which lead to the formation of $\text{MgSiO}_3$, $\text{Mg}_2\text{SiO}_4$ and $\text{SiO}_2$ (see Table 1). Thus, the process of molecule formation in the expanding ejecta is followed at temperatures $T \leq 2 \times 10^4$ K together with the $^{56}\text{Co} \rightarrow ^{56}\text{Fe}$ radioactive decay as the impact with energetic electrons produced during this decay represents the main destruction process of CO molecules.

The formation of dust grains is followed until the temperature of the ejecta has decreased to about 500 K, because at this stage condensation processes are terminated for all solid compounds.

The time evolution of the dust mass synthesized in different compounds is shown in Fig. 3 for three representative PISN progenitor masses, 149$M_\odot$, 195$M_\odot$ and 250$M_\odot$. Dust grains start to condensate when the temperature of the expanding gas has dropped below 2000 K, about 150-
### Table 1. Chemical reactions included in dust formation calculations.

| Solid compound | Chemical reaction |
|----------------|------------------|
| Fe             | Fe(g) $\rightarrow$ Fe(s) |
| Fe$_3$O$_4$    | 3Fe+4O $\rightarrow$ Fe$_3$O$_4$ |
| MgSiO$_3$      | Mg+SiO+2O $\rightarrow$ MgSiO$_3$ |
| Mg$_2$SiO$_4$  | 2Mg+SiO+3O $\rightarrow$ Mg$_2$SiO$_4$ |
| SiO$_2$        | SiO+O $\rightarrow$ SiO$_2$ |
| AC             | C(g) $\rightarrow$ C(s) |

200 days after the explosion (see dotted lines). During this time interval, a fraction of the $^{56}$Co initially present in the ejecta has decayed to Fe. Thus, at the onset of grain condensation, some C atoms are bound in CO molecules and others are available to form amorphous carbon grains. The resulting dust mass is mainly composed by silicates and magnetite grains. Amorphous carbon grains are the first to form, followed by corundum, forsterite, magnetite and ultimately SiO$_2$. This evolutionary sequence simply reflects the different condensation temperatures. The relative abundances of the different grain species depend on the progenitor mass: the 149$M_\odot$ star ejects less iron ($^{56}$Co) than higher mass PISN and thus its final dust composition is characterized by a lower concentration of magnetite and carbon grains (the latter because most of the initial carbon grains are locked in CO molecules).

### 3.1 Final dust masses

The total dust mass formed in different solid compounds and the total mass of CO molecules synthetized in the ejecta as a function of the mass of the stellar progenitor are shown in Fig. 4. For all but the smallest progenitor star, silicate grains appear to be the dominant dust compounds. Indeed, all SiO$_2$ molecules initially present in the ejecta take part in the reactions leading to the formation of forsterite and SiO$_2$ grains and only CO molecules are left at the end of dust condensation. At the lowest mass bin, 140$M_\odot$, the initial $^{56}$Co mass is not large enough to favour the formation of magnetite and amorphous carbon grains and only Al$_2$O$_3$ and Mg$_2$SiO$_4$ grains are formed. At higher initial stellar masses, the larger $^{56}$Co mass ejected by the PISN favours the formation of carbon and magnetite grains and the final mass of CO molecules is correspondingly reduced. Note that MgSiO$_3$ grains are never formed because of the highest condensation temperature and largest nucleation current of Mg$_2$SiO$_4$ grains, which lock all the Mg initially present in the ejecta. Similarly, Fe(s) are never formed because all the Fe which is produced by radioactive decays is locked into magnetite grains. Note that we do not consider the formation of MgO grains which, however, can occur only in the ejecta of the 140$M_\odot$ PISN where Si is less abundant than Mg, and only 40% of the initial Mg mass is depleted onto Mg$_2$SiO$_4$ grains.

### 3.2 Grain size distribution

The final grain size distributions are shown in Fig. 5 for 149 $M_\odot$, 195 $M_\odot$ and 250 $M_\odot$ PISN. The characteristic grain sizes range between $10^{-5}$ and a few 0.1 $\mu$m, depending on the grain species and on the mass of the progenitor star. Each dust grain grows by accretion to a final size which depends on the density regime when condensation occurs (higher densities favoring higher accretion rates) and on the abundance of the key species. Indeed, being the first to condense, amorphous carbon grains tend to have characteristic sizes larger than silicates and magnetite grains. Al$_2$O$_3$ grains are typically small because of the rather low-abundance of Al in the ejecta. Larger mass progenitor systems tend to have larger magnetite grains and smaller amorphous carbon grains. However, the properties of grain size distributions for different progenitor masses depend on the different thermodynamics of the expanding ejecta which affects the relative amplitude of cooling and nucleation rates. The model predicts that, for all progenitor masses, PISN lead to the formation of grains with radii smaller than 1 $\mu$m but systematically larger than the typical sizes of grains formed.

![Figure 4](image-url)
in SNII explosions (Todini & Ferrara 2001) with a reduced scatter among different grain species.

3.3 Depletion factors

The cosmological relevance of dust synthetized in PISN explosions will depend mainly on the global properties of dust rather than on the nature and size of different compounds. In Fig. 6 we show the total dust depletion factor, defined as the dust-to-metal mass ratio released in the explosions, \( f_{\text{dep}} = M_{\text{dust}}/M_{\text{tot}} \) as a function of PISN progenitor mass. With the exception of the smallest mass bin, \( f_{\text{dep}} \) ranges between 0.3 and 0.7 and tends to increase with increasing progenitor mass. In the bottom panel of the same figure, we show the ratio of the total dust mass and the initial progenitor stellar mass. For all but the smallest mass bin, the amount of dust formed is between 15% and 30% of the initial stellar mass. The peculiar behaviour of the 140 \( M_\odot \) progenitor is due to the original elemental composition of its ejecta, which is highly underabundant in Fe and Si and therefore only corundum is synthetized in the final ejecta (see also Fig. 4).

For comparison, in Fig. 7 we show the same quantities but for SNII. Following Todini & Ferrara (2001), we show two cases corresponding to two different values of the total kinetic energy released in the explosion: case A corresponds to the low kinetic energy model \((1.2 \times 10^{51}\text{erg})\) and case B refers to the high kinetic energy model \((1.9 \times 10^{51}\text{erg})\) (see also the original paper of Woosley & Weaver 1995). We also...
assume two different values for the initial metallicity of the progenitor stars, \( Z = 0 \) (dots) and \( Z = Z_\odot \) (squares).

The moderate metal yields in SNII and the effect of fallback of material after the explosion onto the compact remnant lead to depletion factors which are comparable to PISN, with values ranging from 20 \% up to 70 \% for \( Z = 0 \) progenitors with masses \( < 22 M_\odot \). For larger masses, the depletion factor decreases in case B scenarios (higher kinetic energy) because of the larger amount of metals released. For case A scenarios (lower kinetic energy), instead, 25 \( M_\odot \) and 30\( M_\odot \) SNII are predicted to have an \( f_{\text{dep}} \approx 1 \). This is due to the fact that because of fallback, these stars eject only a rather small amount of metals, mostly in the form of carbon, which is completely depleted into AC grains. If the stellar progenitors have solar metallicities, the depletion factor ranges between 10\% and 50\% with a much reduced scatter between case A and B.

In spite of these large depletion factors, the total mass of dust synthesized by PISN is significantly higher than that produced by SNII. Indeed, as already discussed in Todini & Ferrara (2001), in case A scenarios, \( Z = 0 \) SNII synthesize a total dust mass which corresponds to a fraction between 0.3 and 3\% of the original stellar progenitor mass (thus, \( \sim 0.1 - 0.6 M_\odot \) of dust per SN). These values are slightly larger if case B models are considered. When the initial stellar progenitors have solar metallicity, the resulting dust mass is typically a factor \( \sim 3 \) larger than for the metal-free case but it is always less than 6\% of the initial stellar mass.

4 SUMMARY AND DISCUSSION

We have investigated the process of dust formation in the ejecta of first stellar explosions, assuming that the first stars form with characteristic masses of a few 100 \( M_\odot \) and explode as pair-creation SNe. The study is based on an extension of the model developed by Todini & Ferrara (2001) for Type II SNe, which accounts for the different initial chemical compositions of the ejecta and dynamical/thermodynamical properties of the ejecta evolution.

The main results of our analysis can be summarized as follows:

(i) During pair-creation SN explosions, a significant amount of dust is synthesized out of the heavy elements produced in the progenitor stellar interiors during the main sequence lifetime and at the onset of the explosion due to explosive nucleosynthetic processes. The fraction of the original stellar mass which is converted into dust depends on the progenitor mass, with typical values ranging between 15\% and 30\%, resulting in 30\( M_\odot - 60 M_\odot \) of dust produced per SN. These values are much larger than those found for \( Z = 0 \) Type II SNe resulting from stars with masses between 12 \( M_\odot \) and 40 \( M_\odot \) (0.1\( M_\odot - 0.6 M_\odot \)), even if these stars are assumed to be of solar metallicity (0.1\( M_\odot - 1.8 M_\odot \)).

(ii) Because of the large amount of metals released in PISN explosions, dust depletion factors, defined as the dust-to-metal mass ratios, range between 30\% and 70\% depending on the progenitor mass.

(iii) The composition of the dust compounds depends critically on the thermodynamics and initial composition of the ejecta, i.e. on the progenitor mass. For the assumed temperature evolution, grain condensation starts 150-200 days after the explosion and silicates, magnetite and AC grains are formed. The dominant compounds for all progenitor masses are SiO\(_2\) and Mg\(_2\)SiO\(_4\) while the contribution of amorphous carbon and magnetite grains grows with progenitor mass.

(iv) PISN explosions lead to the formation of grains with typical sizes which range between 10\(^{-3}\) and a few 0.1\( \mu m \); for all progenitors, grains radii are always smaller than 1 \( \mu m \) but the relative grain size distribution change depending on the thermodynamics and abundance of the relevant key species. As a general trend, corundum represents the smallest-size compound, amorphous carbon grains tend to form with the largest radii and silicates and magnetite grains have intermediate sizes.

The above results have been obtained under the assumption that the heavy elements present in the ejecta at the onset of the explosion are uniformly mixed up to the outer edge of the helium core. In previous dust formation models (Kozasa et al. 1989; Todini & Ferrara 2001) this approximation was motivated by the early emergence of X-rays and \( \gamma\)-rays in SN 1987A, which suggested mixing in the ejecta at least up to the helium core edge (Kumagai et al. 1988). The use of multi-dimensional hydrodynamic codes to model the observed light curves has made clear that mixing occurs on macroscopic scales through the development of Rayleigh-Taylor instabilities: these instabilities arise at the interface between elemental zones and grow nonlinearly to produce (i) fingers of heavy elements projected outwards with high velocities and (ii) mixing of lighter elements down to regions that have lower velocities (Woosden 1997). As a result, the gas in the ejecta is mixed into regions which are still chemically homogeneous and which cool with different timescales, whereas only small clumps in the ejecta are microscopically mixed. Such a structure affects the process of dust formation, changing both the total amount of dust formed and the relative abundance of different solid compounds, as recently shown by Nozawa et al. (2004).

A related aspect of the model which requires deeper investigation is the assumed temperature structure of the gas within the ejecta. The adopted thermal evolution of the expanding ejecta is motivated by the results of numerical simulations of the internal structure of PISN progenitors (Fryer, Woosley & Heger 2001; Heger & Woosley 2002) and models the impact of the decays of radioactive elements through the change of the adiabatic index from \( \gamma = 4/3 \) to \( \gamma = 5/3 \) assumed to occur at \( ^{56}\text{Co} \) e-folding time (111.26 days after the explosion). A comparable thermal history is found by Nozawa et al. (2003) solving the radiative transfer equation and taking into account the energy deposition by radioactive elements. For the same PISN progenitor mass, however, their normalization is slightly higher (by a factor \( \sim 3 \)) because of the different input stellar models (Umeda & Nomoto 2002).

Finally, to quantify the cosmic relevance of dust formation in the early Universe, we should restrict the analysis to the fraction of the newly formed dust which is able to survive the impact of the reverse shock, following thereafter the fate of the surrounding metal-enriched gas. The process of dust sputtering dissociates the grains into their metal components and might have an important role in cosmic metal enrichment (Bianchi & Ferrara 2004). However, new theoretical models seem to indicate that the post-shock tempera-
ture enters the regime suitable for dust condensation inside the oxygen layer, because of the high cooling efficiency of this element, but remains substantially higher in the outer He and H layers. If this is the case, then the reverse shock might lead to an increase in the total amount of dust formed rather than decreasing it.

5 COSMOLOGICAL IMPLICATIONS

Our analysis shows that if the first stars formed according to a top-heavy IMF and a fraction of them exploded as pair-creation supernovae, a large amount of dust is produced in the early Universe. In this section, we discuss some of the main cosmological implications of this result, with particular emphasis on its role in the thermodynamics of the gas that will be later incorporated into subsequent generations of objects.

Recent numerical and semi-analytical models for the collapse of star-forming gas clouds in the early Universe have shown that because of the absence of metals and the reduced cooling ability of the gas, the formation of low-mass stars is strongly inhibited. In particular, below a critical threshold level of metallicity of $Z_{\text{crit}} = 10^{-4}Z_\odot$ cooling and fragmentation of the gas clouds stop when the temperature reaches a few hundreds K (minimum temperature for H$_2$ cooling) and the corresponding Jeans mass is of the order of $10^4 - 10^5M_\odot$ (Schneider et al. 2002). Gas clouds with mass comparable to the Jeans mass start to gravitationally collapse without further fragmentation, until a central protostellar core is formed which rapidly grows in mass through gas accretion from the surrounding envelope. The absence of metals and dust in the accretion flow and the high gas temperature favour very high accretion efficiencies and the resulting stars can be as massive as 600 $M_\odot$ (Omukai & Palla 2003).

As the gas becomes more and more enriched with heavy elements, the cooling rate increases because of metal (especially C and O) line emission. More importantly, if a fraction of the available metals is depleted onto dust grains, dust-gas thermal exchanges activate a new phase of cooling and fragmentation which enables the formation of gas clumps with low-mass (Schneider et al. 2003). In particular, if the metallicity of the star forming gas clouds exceeds $10^{-4}Z_\odot$, this dust-driven cooling pathway is irrelevant because cooling via metal-line emission by itself is able to fragment the gas down to characteristic Jeans masses in the range $10^{-2} - 1M_\odot$. At the same time, if the metallicity of the gas is below $10^{-5}Z_\odot$, even if all the available metals are assumed to be depleted onto dust grains, the resulting cooling efficiency is too low to activate fragmentation and the resulting Jeans masses are as large as in the metal-free case ($10^3 - 10^4M_\odot$). Thus, we can conclude that the presence of dust is crucial to determine the final mass of stars forming out of gas clouds with metallicities in the critical range $Z_{\text{crit}} = 10^{-5}Z_\odot$. As a reference value, for a metallicity of $Z = 10^{-4}Z_\odot$, 20% of the metals are depleted onto dust grains ($f_{\text{dep}} = 0.2$) the resulting mass of the collapsing clouds is reduced to $10^{-2} - 10^{-3}M_\odot$ and can lead to low-mass stars. This is fully consistent with the predicted dust mass formed from PISN progenitors (see Fig. 6).

Also, we can not neglect that our models predict the formation of a significant amount of CO molecules, which can contribute to gas cooling. This aspect needs to be investigated further though we expect that the presence of CO molecules will be complementary to that of dust in the critical range of metallicities.

Therefore, in the emerging picture of galaxy evolution, the first episodes of star formation were characterized by very massive stars forming according to a top-heavy IMF. It is only when the metals and dust ejected by the first pair-creation supernovae are able to pollute a substantial fraction of the IGM, that an overall transition to a normal IMF forming stars with masses comparable to those that we presently observe in the nearby Universe occurs. The epoch of this transition depends crucially on the process of metal enrichment through the so-called chemical feedback: within metal-enriched regions, if the metallicity lies within the critical range, the presence of dust becomes critical and can no longer be neglected in the thermodynamics of the star forming gas. It is very likely that the transition will not occur at a single redshift because of the highly inhomogeneous process of metal enrichment (Scannapieco, Schneider & Ferrara 2003) and that there will be epochs when the two modes of star formation will be coeval in different regions of the Universe.

This in turns might be very important for the reionization history of the IGM. Indeed, very massive metal-free stars are powerful sources of ionizing photons and an early epoch of star formation with a top-heavy IMF can easily match the required high optical depth to electron scattering measured by WMAP (Kogut et al. 2003; Spergel et al. 2003; for a general discussion see Ciardi, Ferrara & White 2003). However, an early epoch of reionization is difficult to reconcile with the observed Gunn-Peterson effect in the spectra of $z > 6$ quasars (Fan et al. 2002) which implies a mass averaged neutral fraction of $\sim 1\%$. These two observational constraints seem to indicate that the reionization history of the Universe might have been more complex than previously thought, with probably two distinct epochs of reionization separated by a relatively small redshift interval in which the Universe might have recombined again. This intermediate epoch of recombination could be the result of a decrease in the ionizing power of luminous sources, probably due to their metal-enrichment and consequent IMF transition.

An early epoch of reionization, as required by WMAP data, poses another critical issue: after reionization, the temperature of the IGM starts to decline as a consequence of cosmic expansion. By the time it reaches the observable range of redshifts $z < 6$ the temperature of the IGM might be too low to match the observed thermal history (Schaye et al. 2000). The presence of a significant amount of dust synthesized by the first very massive supernovae might be extremely important to raise the IGM temperature through dust photoelectric heating. To estimate the amount of dust in the IGM required to match the observed thermal history, it is necessary to make specific assumptions about the UV background radiation, the reionization history of the IGM and the grain composition and size distribution (Inoue & Kamaya 2003). Furthermore, the properties of dust grains in the IGM may differ from those directly predicted by dust formation models as a consequence of specific selection rules in the transfer of grains from the host galaxies to the IGM (see Bianchi & Ferrara 2004, who find that only grains larger
Dust Formation in Very Massive Primordial Supernovae

Figure 8. The number of PISN required to pollute a host protogalaxy with a dust-to-gas ratio equal to 5% of the galactic value is shown as a function redshift (solid line). In the same panel, we show the total mass of the host halo which correspond to a virial temperature of 1000 K (dashed line).

than ≈ 0.06μm are preferentially ejected in the IGM). These complications are beyond the scope of the present analysis.

Finally, it is well known that the presence of dust at high redshifts offers an alternative formation channel for molecular hydrogen, the dominant coolant in the early Universe, which, in the absence of dust, can form only from the gas phase. In small protogalaxies, the H$_2$ formation rate on grain surface becomes dominant with respect to the formation rate from the gas phase, when the dust-to-gas ratio exceeds roughly 5% of the galactic value (Todini & Ferrara 2001). From this order of magnitude estimate, we can derive the number of pair-creation supernovae required to enrich a small protogalaxy to this level. The results are shown in Fig. 8, where we have assumed the host galaxy to correspond to a halo with virial temperature of 1000 K and we have considered the dust mass synthesized by a 195 $M_\odot$ progenitor (see Fig. 4) as representative of dust formation efficiencies in PISN. This simple estimate shows that in the redshift range relevant to these small protogalactic systems ($z > 10 - 15$), one PISN is required to pollute the gas with enough dust that H$_2$ formation on grain surface starts to be important. This, in turn, might have very important consequences for the star formation activity at high redshift (Hirashita & Ferrara 2002).

ACKNOWLEDGEMENTS

This work was based on the code developed by P. Todini, whose support we wish to gratefully acknowledge. We also thank A. Heger and T. Kozasa for fruitful information and the anonymous referee for valuable suggestions and careful reading of the paper. We acknowledge support from the CNR/JSPS Italy-Japan Seminar Program.
