ABSTRACT

We present observations of an H i cloud complex most likely located in the Virgo galaxy cluster, first reported by Kent et al. The complex consists of five clouds, detected in the dataset of the ALFALFA extragalactic H i survey at Arecibo. The clouds have radial velocities between \( c z_o \sim 480 \) and 610 km s\(^{-1}\). At the Virgo cluster distance, they are spread over a projected span of 170 kpc and have H i masses ranging from 0.48 to 1.7 \( \times 10^8 \) \( M_\odot \). The overall H i mass of the complex is 5.1 \( \times 10^8 \) \( M_\odot \). The clouds’ velocity widths vary between 50 and 250 km s\(^{-1}\). New results of follow-up aperture synthesis observations conducted with the Very Large Array are also presented, which yield a higher-resolution view of two of the clouds in the complex. These two resolved clouds show no evidence of symmetry in the gas distribution or of any ordered motions. The possibility that the complex is a group of primordial objects, embedded in their own dark matter halo is thought to be unlikely. Scenarios in which the clouds have been removed from the disk of a galaxy traveling at high speed through the intracluster medium are considered. The most likely among those is thought to be one where the clouds were separated from NGC 4445 at a time greater than 5 Gyr ago. The orbital velocity of the clouds and the putative parent galaxy would now be seen at a relatively large angle with respect to the line of sight.

Key words: galaxies: clusters: general – galaxies: halos – galaxies: individual (NGC 4445, NGC 4424) – galaxies: interactions – intergalactic medium – radio lines: galaxies

1. INTRODUCTION

The study of the cold gas content in extragalactic systems plays an important role in understanding their formation and evolution. Not only does the gas reveal information on the star formation potential of a galaxy, it can also help trace the dynamic history and response to the surrounding environment, whether it inhabits a dense cluster or an unpopulated field. For example, the fingerprint of galactic collisions and ram pressure stripping effects can be seen in the form of detached gaseous fragments and clumps. The 21 cm spectral line of hydrogen can also be detected as a redshift indicator and kinematical probe. The H i feature, VirgoHI21, was detected north of the spiral galaxy NGC 4254 (Minchin et al. 2005) and interpreted as a fairly massive “dark galaxy.” Arecibo Legacy Fast ALFA (ALFALFA) survey data, which provide full coverage of the region, indicate that VirgoHI21 is not an isolated dark galaxy, but rather a tidal tail of NGC 4254 resulting from the high-speed encounter of that galaxy with a now distant interloper (Haynes et al. 2007; Duc & Bournaud 2008).

A galaxy traveling through a cluster can be affected by a variety of mechanisms, the most commonly invoked being ram pressure stripping. The study of H i deficiency in Virgo spirals was pioneered by Davies & Lewis (1973), with the first reliably measured deficiencies reported by Chamaraux et al. (1980). Giovanelli & Haynes (1983) showed that H i deficient galaxies in Virgo had truncated H i disks. These results were extended to other clusters (Giovanelli & Haynes 1985; Haynes & Giovanelli 1986; Haynes et al. 1984) and mapped with higher resolution (Cayatte et al. 1990; Chung et al. 2007). Oosterloo & van Gorkom (2005) recently...
reported the discovery of a H\textsubscript{i} cloud in the vicinity of the Virgo spiral NGC 4388 with a H\textsubscript{i} mass of \(3.4 \times 10^8\) \(M_\odot\), resolved into distinct clumps. They show a clear connection to NGC 4388. It has also been shown that galaxies can be “harassed” by the collective effect of the cluster potential and multiple high speed encounters with other cluster members (e.g., Moore et al. 1996; Mihos et al. 2005). The hot intracluster gas is a hostile environment for the cold material removed from cluster galaxies through these processes. The interaction remnants represented by the latter are thus transient features. A full census of their number and estimates of longevity can provide insights on the metal enrichment of the intracluster gas.

Virgo is the nearest rich cluster of galaxies, thus providing the best target for the detailed study of many environment-driven effects on the evolution of galaxies. With over 1300 cataloged detections (Binggeli et al. 1985), the overdensity associated with the Virgo cluster extends over more than 300 deg\(^2\) in the sky, distributed in several subclumps. The largest two clumps are centered around large elliptical galaxies, M87 for the main clump, and M49 for the southern subclump. The morphology-density relation is well established in the cluster, with late-type objects thought to be still falling into the cluster, as it dynamically evolves. The dynamically vulnerable, extended H\textsubscript{i} disks of late-type galaxies can be easy victims of the processes discussed above. Optical data bases, such as the Digital Sky Survey (Lasker et al. 1990) and the Sloan Digital Sky Survey (York et al. 2000), provide photometry and targeted spectroscopy of cluster objects, as does the compendium of Virgo galaxies data of GOLDMINE Web site (Gavazzi et al. 2003; http://goldmine.mib.infn.it/). Individual galaxy distances are growing in number thanks to the ACS Virgo Cluster survey, which focuses on early-type galaxies via the surface-brightness fluctuation method (Mei et al. 2007). Targeted H\textsubscript{i} surveys also have played an important role in the overall characterization of the cluster (see, e.g., GOLDMINE for references).

The H\textsubscript{i} Parkes All-Sky Survey (HI PASS; Barnes et al. 2001) has mapped 30,000 deg\(^2\), part of which covers Virgo in the region 12\textdegree\textquoteright\textless\alpha\textless13\textdegree\ and +2\textdegree\textless\delta\textless+20\textdegree. HIPASS catalogs available from NED list 125 galaxies in this region. The ALFALFA Survey (Giovanelli et al. 2005) is more sensitive and has significantly higher angular and spectral resolution than HIASS. It is thus providing a much more incisive look into the H\textsubscript{i} properties of the cluster. While the H\textsubscript{i} content of many individual spiral galaxies has been mapped in detail with interferometry (Cayatte et al. 1990, 1994; Chung et al. 2007), no survey has covered the Virgo cluster region with the sensitivity and completeness of ALFALFA. It is a primary goal of the ALFALFA survey to study and characterize the local H\textsubscript{i} universe, including the Virgo cluster. ALFALFA will provide a fair, well-sampled and homogenous spectral dataset, covering 7000 deg\(^2\) of the high galactic latitude sky out to a redshift of \(cz\sim18,000\) km s\(^{-1}\). Approximately 250 deg\(^2\) of the Virgo cluster in the range 11\textdegree\textless\alpha\textless13\textdegree, 8\textdegree\textless\delta\textless16\textdegree\, has been completely surveyed as of late 2007, with catalogs of extracted source parameters already released for publication (Giovanelli et al. 2007; Kent et al. 2008). A key feature of the survey is its sensitivity to low H\textsubscript{i} mass objects—ALFALFA will provide a complete H\textsubscript{i} census down to \(2 \times 10^5\) \(M_\odot\) at the Virgo distance. Sampling the low-mass population will be key in determining the H\textsubscript{i} mass function in the cluster environment, as well as in the field. The ALFALFA dataset in Virgo has already yielded many new interesting results (Kent et al. 2007; Haynes et al. 2007; Koopmann et al. 2008). In this paper we give a detailed description of a multicomponent H\textsubscript{i} cloud complex in the Virgo cluster region initially reported by Kent et al. (2007). In Section 2 we describe the observations and data reduction method within the context of ALFALFA and the cloud detections made with that dataset. In Section 3 we detail follow-up observations conducted with the Very Large Array (VLA)\(^{11}\). In Section 4 we discuss CO observations of the cloud. Section 5 discusses the environment of the cloud complex. Section 6 discusses possible formation mechanisms for the cloud complex. Section 7 summarizes the results of the paper. Throughout the paper we assume a distance to the Virgo Cluster of \(D_\odot = 16.7\) Mpc, and refer to the heliocentric reference frame for all velocities.

2. DISCOVERY OF A H\textsubscript{i} CLOUD COMPLEX

The ALFALFA observing strategy is described in detail by Giovanelli et al. (2005). The data are obtained in a meridian transit drift mode with the ALFA. Raw scans consist of 14 spectra (7 beams \(\times 2\) linear polarizations beam\(^{-1}\)), sampled at a rate of 1 Hz. The spectra span a 100 MHz bandwidth with 4096 channels per polarization, centered at 1385 MHz. The resulting spectral resolution is 24.4 kHz before smoothing, corresponding to \(\delta V = 5.1\) km s\(^{-1}\) at the rest frequency of the 21 cm H\textsubscript{i} line. Scans are calibrated, baselined, and flagged for radio frequency interference, and then combined into regularly sampled data cubes.

Details of the ALFALFA data processing can be found in Kent (2008). Briefly, frequency channels in each grid have been baselined with linear fits and then “flatfielded,” where a median subtraction has been performed in both the right ascension and declination directions. A matched-filter algorithm was used for signal detection, with manual follow-up (Saintonge 2007). The careful attention to signal extraction, analysis, and data quality has proven to be invaluable in detecting faint objects and optimizing the output of the signal extraction process.

The cloud complex was discovered in the ALFALFA data obtained in the Spring 2005 campaign, which sampled the Virgo core region \((12\textdegree < \alpha < 13\textdegree, 8\textdegree < \delta < 16\textdegree)\). The data presented here are taken from a 2\textdegree\times2\textdegree data cube centered at \(\alpha = 12\textdegree20\text{m}, \delta = 9\textdegree00\text{'}\, (J2000)\). The system temperatures of the ALFA receivers during the observations were in the range 26 K < \(T_{sys} < 30\) K, yielding a root mean square (rms) noise of \(\sigma_{\nu} = 2.5\) mJy beam\(^{-1}\) in channels with \(\delta V = 5.1\) km s\(^{-1}\). The characteristics of the ALFALFA data cube from which the data are taken are summarized in Table 1.

\(^{11}\) The VLA is a facility of National Radio Astronomy Observatory, which is operated by Associated Universities, Inc., under a cooperative agreement with the National Science Foundation.
2.1. ALFALFA Observations

The cloud complex is located near $\alpha \sim 12^h30^m$, $\delta \sim 9^\circ30'$—this places it 2.9 (845 kpc in projection) South of M87 and 1.5 (432 kpc in projection) north of M49. We discuss the optical environment of the cloud complex in Section 5.

The complex consists of five distinct emission features or “clouds,” which we denote C1–C5. Together, they span approximately 35' (170 kpc in projection at the cluster distance) on the sky and 130 km s$^{-1}$ in velocity. Channel maps of the ALFALFA dataset in the vicinity of these detections are shown in Figure 1, and total intensity (zeroth moment) and intensity-weighted velocity maps of the region is in Figure 2. An integrated spectral profile for each cloud is presented in Figure 3.

The individual properties of the clouds derived from the ALFALFA data are given in Table 2; all parameters are computed in the manner described by Giovanelli et al. (2007). The spatial centroid of each cloud is in Column (2). Its accuracy depends on the source strength, and varies from an average of $\sim 15''$ for the brightest features to $\sim 30''$ for the faintest ones. The heliocentric velocity $cz_{\odot}$, width at 50% of the peak $W_50$ and total flux $F_c$ of the integrated spectral profiles in Figure 3 are in Columns (3)–(5). The signal-to-noise ratio (S/N) of the detections is in Column (6), and is given by

$$ S/N = \left( \frac{1000 F_c}{W_{50}} \right)^{1/2} \frac{w_{\text{smo}}}{\sigma_{\text{rms}}} , $$

where $F_c$ is in Jy km s$^{-1}$, $W_{50}$ is in km s$^{-1}$, $w_{\text{smo}}$ is a smoothing width equal to the number of 10 km s$^{-1}$ bins bridging half the signal, and $\sigma_{\text{rms}}$ is the rms noise (in mJy) across the integrated spectrum at 10 km s$^{-1}$ resolution. The H I mass $M_{HI}$ for each cloud is in Column (7), and is computed assuming that the clouds are optically thin and at the Virgo distance $D_V = 16.7$ Mpc:

$$ M_{HI}/M_{\odot} = 2.356 \times 10^5 D_V^2 F_c , $$

where $D_V$ is in Mpc and $F_c$ is in Jy km s$^{-1}$. The uncertainties on $M_{HI}$ in Table 2 and elsewhere do not include that in the distance adopted, which is poorly constrained due to the large peculiar velocities of objects near or within the cluster.

2.2. Cloud Morphologies and Kinematics from ALFALFA Data

Cloud C1: C1 is the main cloud in the complex and the highest S/N detection in this region. It is marginally resolved by the ALFA beams (Figure 2). Its integrated profile is symmetric
Figure 2. Global H\textsc{i} distribution and kinematics of the cloud complex. (a) One square degree total intensity (zeroth moment) map of the cloud complex field. The cloud identifiers from Table 2 are indicated. The H\textsc{i} contours are 50, 100, 200, 300, 400, 500, 600, 800, 1000, 1200, 1400, and 1600 mJy km s\(^{-1}\) beam\(^{-1}\). The background image is taken from the second generation Digital Sky Survey B-band plates (Lasker et al. 1990). The ellipse in the lower left indicates the ALFALFA beam size (3.3' × 3.8'). (b) Intensity-weighted velocity (first moment) map. The linear scale bar ranges from 416–745 km s\(^{-1}\). Contours indicate 450, 500, 550, 600, 650, and 700 km s\(^{-1}\).

Table 2

| Cloud | \(\alpha, \delta\) (J2000) | \(c_{20}\) (km s\(^{-1}\)) | \(W_{50}\) (km s\(^{-1}\)) | \(F_c\) (Jy km s\(^{-1}\)) | S/N | \(\log(M_{\text{HI}}/M_\odot)\) |
|-------|----------------|----------------|----------------|----------------|-----|----------------|
| C1    | 12 30 25.8, +09 28 01 | 488 ± 5      | 62 ± 11       | 2.48 ± 0.07   | 21.2| 8.21           |
| C2    | 12 31 19.0, +09 27 49 | 607 ± 4      | 56 ± 7        | 0.72 ± 0.06   | 6.5 | 7.67           |
| C3    | 12 29 42.8, +09 41 54 | 524 ± 7      | 116 ± 15      | 1.16 ± 0.07   | 8.6 | 7.87           |
| C4    | 12 30 19.4, +09 35 18 | 603 ± 4      | 252 ± 7       | 2.56 ± 0.09   | 13.1| 8.22           |
| C5    | 12 31 26.7, +09 18 52 | 480 ± 10     | 53 ± 21       | 0.91 ± 0.06   | 7.6 | 7.77           |

Notes. Column (1): cloud name. Column (2): right ascension and declination of cloud centroid (J2000). Column (3): average heliocentric velocity of integrated spectral profile from Figure 3. Column (4): profile width, measured at 50% of the integrated spectra profile peak and corrected for instrumental broadening as described in Giovanelli et al. (2007). Column (5): total flux of integrated spectral profile. Column (6): signal-to-noise ratio of the detection, computed using \(W_{50}\) and \(F_c\) via Equation (1). Column (7): base 10 logarithm of total H\textsc{i} mass, computed using \(F_c\) via Equation (2).

and narrow with a peak flux density of 38 mJy (Figure 3). C1 has one of the largest H\textsc{i} masses in the complex at \(M_{\text{HI}} = (1.62 ± 0.04) \times 10^8 M_\odot\). There is a faint, uncataloged optical feature visible in Sloan Digital Sky Survey (SDSS) images in the vicinity of C1; its relationship to the H\textsc{i} cloud is discussed in Section 5.

Cloud C2: This isolated cloud is the faintest ALFALFA detection in the region at S/N = 6.5, and it has the lowest H\textsc{i} mass. C2 is close to the ImV dwarf galaxy VCC 1357 (Binggeli et al. 1985), but the ALFALFA centroid is offset from the optical position of the latter by 2' to the west. No optical redshift is available for VCC 1357. An Arecibo single-beam observation centered on VCC 1357 with similar sensitivity to the ALFALFA data is presented by Hoffman et al. (1987). The properties of their detection are identical to those of C2 within the measurement uncertainties; these and the ALFALFA observations have likely uncovered the same object. However, the previous association of VCC 1357 with this H\textsc{i} source is now in doubt by the evidence for an offset in position between the two, and by the detection of the other H\textsc{i} complex clouds presented here. The positional offset between VCC 1357 and C2 is confirmed by the VLA data discussed in the next section. The possible relationship between C2 and VCC 1357 is discussed in Section 5.

Cloud C3: This northernmost component of the complex is unresolved by the ALFA beam. Its integrated profile appears
Cloud C5: This cloud is located 17.4 southeast of the main cloud C1. Its integrated profile appears to be symmetric, and implies an H\textsubscript{i} mass that is a third of C1 at \( M_{\text{H}\textsubscript{i}} = (5.9 \pm 0.4) \times 10^7 M_\odot \). At the ALFALFA sensitivity, C5 is not connected with any other complex clouds. There is no discernible optical counterpart to C5 in the SDSS or DSS survey images of the region.

3. APERTURE SYNTHESIS FOLLOW-UP OBSERVATIONS

Aperture synthesis observations of the central region of the cloud complex detected by ALFALFA were obtained with the VLA in two campaigns. On 2005 July 11, 5 hr on-source were obtained via rapid response observations in C configuration. On 2006 January 18–23, dynamically scheduled observations during the D–A configuration change yielded \( \sim 1.5 \) hr on-source with antennas that had not yet been moved. All observations had common pointing and spectral centers of \( \alpha = 12^h30^m45^s \), \( \delta = +9^\circ26^\prime0^\prime\prime \) (J2000) and \( \nu = 1417 \) MHz, and online Hanning smoothing was applied to yield 48.8 kHz channels over a total bandpass of 3.125 MHz. The observing setup was chosen to maximize the number of ALFALFA cloud detections accessible to the VLA in a single pointing: all of the clouds in Table 2 except C3 fall within the resulting field-of-view and bandpass. The data from the runs was reduced using the Astronomical Image Processing System (AIPS; Greisen 2003). Standard flux, phase and bandpass calibration routines were applied. Continuum emission was removed from the data via linear fits to the average visibilities in line-free channels spanning 245 kHz at either end of the calibrated bandpass, yielding a net bandwidth of 2.2 MHz sensitive to H\textsubscript{i} emission.

After calibration, the data from each run were combined into a single UV data cube and imaged using a variety of spatial and spectral weighting schemes. The dirty beam pattern was deconvolved from the data using the Multi-Scale Clean algorithm implemented in AIPS (Cornwell 2008), in which components are extracted from a series of tapered images of the visibilities. We find that the resulting maps are not sensitive to the details of the deconvolution process, and therefore analyze the highest sensitivity, naturally-weighted cube with a synthesized beam width of 22\arcsec (1.8 kpc at the Virgo distance). All maps and derived parameters are corrected for the attenuation of the primary beam, and averaged over two or three spectral channels to yield resolutions of \( \delta V' = 20.7 \) km s\(^{-1}\) or \( \delta V' = 31.0 \) km s\(^{-1}\), respectively. A summary of the aperture synthesis observing and map parameters is given in Table 3. For clarity, all variables denoting parameters derived from the VLA observations are primed.

3.1. H\textsubscript{i} Aperture Synthesis Detections

We make two detections in the VLA data, which correspond to the clouds C1 and C2 identified in the ALFALFA survey data. Channel maps of these detections are shown in Figures 4 and 5. Contours are at multiples of the median rms map noise
Table 3
Aperture Synthesis Observing and Data Cube Parameters

| Parameter                  | Value                  |
|----------------------------|------------------------|
| Pointing center (J2000)    | 12:30:45.4 ±09:26:00   |
| Total time on-source       | 265 minutes            |
| Net bandpass               | 2.2 MHz (378–822 km s\(^{-1}\)) |
| Maximum spectral resolution \(\delta V\) | 48.8 kHz (10.3 km s\(^{-1}\)) |
| Natural Weighting:         |                        |
| Synthesized beam           | 22\(^{\circ}\) × 20\(^{\circ}\) @ –20\(^{\circ}\) |
| \(\sigma_m\) at pointing center, \(\delta V = 20.7 \text{ km s}^{-1}\) | 0.33 mJy beam\(^{-1}\) |
| \(\sigma_m\) at pointing center, \(\delta V = 31.0 \text{ km s}^{-1}\) | 0.29 mJy beam\(^{-1}\) |

\(\sigma_m\) in the primary beam-corrected maps at that location, and negative contours are indicated by dashed lines. We find that the emission associated with C1 and C2 spans multiple synthesized beams over contiguous (but largely independent\(^{12}\)) channels irrespective of the visibility weighting or image deconvolution scheme adopted; they are credible detections in the VLA data.

Total intensity and intensity-weighted velocity maps for the clouds are shown in Figures 6 and 7. The data cubes are blanked before these moments are computed: a mask is generated for each frequency channel by smoothing the data to half the angular resolution in Table 3 and blanking regions with fluxes less than 2\(\sigma_m\) of that image. In addition, the intensity-weighted velocity maps in Figures 6(b) and 7(b) are computed only at locations with column density \(N_H' > 10^{20} \text{ cm}^{-2}\). Integrated spectral profiles for C1 and C2 from the VLA observations are in Figure 8. The 1\(\sigma\) error bars on each point in Figure 8 reflect \(\sigma_m\) integrated over the emission region in that channel and a 5% calibration uncertainty.

The properties of C1 and C2 derived from the VLA data are given in Table 4. Unless otherwise indicated, the parameters are computed in the same manner as their ALFALFA counterparts (see Section 2.1). The location of the peak \(N_H'\) in the total intensity maps of Figures 6(a) and 7(a) is given in Column (2). The centroid \(cz\) of the integrated profiles of Figure 8 is in Column (3), and \(W50'\) of the profiles is in Column (4). The values of \(W50'\) are corrected for instrumental effects by assuming that the unbreayed profile is gaussian. The integrated flux density \(F\) and \(H_1\) mass \(M_{H_1}\) are in Columns (5) and (8), respectively. The maximum angular extent \(\delta\) of each cloud is in Column (6). We adopt the outermost locations where \(N_H' = 10^{20} \text{ cm}^{-2}\) in Figures 6(a) and 7(a) as the cloud edges, and correct the measured values for beam smearing. The position angle \(PA_H\) at which \(\delta\) is measured is in Column (7).

An estimate of the dynamical mass \(M_{dyn}'\) of each cloud is in Column (9), and is computed via

\[
M_{dyn}' = (3.39 \times 10^4) a_{H_1}' D_V \left(\frac{W50'}{2}\right)^2, \tag{3}
\]

where \(a_{H_1}'\) is the object diameter in arcminutes, \(W50'\) is in \(\text{km s}^{-1}\) and the Virgo distance \(D_V\) is in Mpc. We note that \(M_{dyn}'\) has physical meaning only if the clouds are self-gravitating and in dynamical equilibrium; these two assumptions may not be valid for C1 and C2 (see Section 6).

Position–velocity slices through the C1 and C2 datacubes are shown in Figures 9 and 10, respectively. For C1 in Figure 9, one 3\(^{\circ}\) wide slice is oriented along \(PA_H\), and the other is perpendicular to this axis. We note that the emission is unresolved both spatially and spectrally along the axis perpendicular to \(PA_H\) for C2, and we therefore show only the slice oriented along \(PA_H\) in Figure 10.

3.2. \(H_1\) Morphologies and Kinematics of C1 and C2

The VLA follow-up data provide important insight into the \(H_1\) morphologies and kinematics of C1 and C2.

**Cloud C1:** Figures 4 and 6(a) show that C1 has a disordered morphology at the resolution of the VLA observations, with the bulk of the emission stemming from an arclike structure at...
Figure 5. Naturally-weighted channel maps for C2 from the VLA observations. The plotted channels are independent ($\delta V' = 20.7 \text{ km s}^{-1}$). Contours are at $0.46 \times (-3, -2, 2, 3, 4, 5, 6) \text{ mJy beam}^{-1}$; negative contours are represented with dashed lines. The cross denotes the C2 centroid in the ALFALFA data (Table 2), and the star denotes the optical position of VCC 1357 (Binggeli et al. 1985). The heliocentric radial velocity is in the upper right corner of each panel, and the synthesized beam is in the lower left corner of the first panel.

(A color version of this figure is available in the online journal.)

Figure 6. H\textsubscript{i} distribution and kinematics of C1 in the VLA data. (a) Total intensity map of C1 (contours) superimposed on an SDSS g image (grayscale). Contours are at $N_{\text{HI}}' = 10^{20} \times (1, 1.5, 2, 2.5, 3) \text{ cm}^{-2}$, and the grayscale is plotted logarithmically. A very faint, uncatalogued source in the optical image is enclosed by the box. The cross indicates the centroid of the Arecibo detection for C1. The synthesized beam is in the lower left corner of the panel. (b) Intensity-weighted velocity map of C1 in regions where $N_{\text{HI}}' \geq 10^{20} \text{ cm}^{-2}$. The grayscale spans 470–505 km s$^{-1}$ on a linear scale, as indicated by the wedge at the top of the plot. Contours are at (480, 490, 500, and 510) km s$^{-1}$.

(A color version of this figure is available in the online journal.)

Table 4
Aperture Synthesis Cloud Properties from the VLA Observations

| Feature | ($\alpha, \delta$)\textsubscript{(J2000)} | $cz_{\odot}$ (km s$^{-1}$) | $W50'$ (km s$^{-1}$) | $F_c'$ (Jy km s$^{-1}$) | $a_{\text{HI}}$ (') | $PA_{\text{HI}}$ (') | log($M_{\text{HI}}'/M_\odot$) | log($M_{\text{dyn}}'/M_\odot$) |
|---------|-----------------------------------|----------------------------|-----------------|----------------------|----------------|----------------|-----------------|----------------|
| C1      | 12\textsubscript{30} 24 +09\textsubscript{28} 20 | 488 ± 6                   | 78 ± 11         | 2.14 ± 0.07          | 2.7 ± 0.3     | 36             | 8.15            | 9.36            |
| C2      | 12\textsubscript{31} 18 +09\textsubscript{29} 25 | 597 ± 3                   | 38 ± 5          | 0.57 ± 0.06          | 1.5 ± 0.3     | 146            | 7.57            | 8.48            |

**Notes.** Column (1): cloud name. Column (2): right ascension and declination of the peak $N_{\text{HI}}'$ (J2000). Column (3): average heliocentric velocity of integrated spectral profile from Figure 8. Column (4): profile width, measured at 50% of the integrated spectral profile peak and corrected for instrumental effects assuming that unbroadened profile is gaussian. Column (5): total flux of integrated spectral profile. Column (6): maximum linear extent of region with $N_{\text{HI}}' \geq 10^{20} \text{ cm}^{-2}$ in the total intensity maps (Figures 6(a) and 7(a)). Column (7): position angle at which $a_{\text{HI}}$ was measured. Column (8): base 10 logarithm of total H\textsubscript{i} mass, computed using $F_c'$ via Equation (2). Column (9): base 10 logarithm of the dynamical mass, computed using $W50'$ and $a_{\text{HI}}$ via Equation (3).
Figure 7. HI distribution and kinematics of C2 in the VLA data. (a) Total intensity map of C2 (contours) superimposed on an SDSS g image (grayscale). Contours are at $N'_{\text{HI}} = 10^{20} \times (0.75, 1, 1.25, 1.5, 2, \text{and} 2.25) \text{ cm}^{-2}$, and the grayscale is plotted logarithmically. The star indicates the location of VCC 1357 (Binggeli et al. 1985); it is just visible in the optical image. The synthesized beam is in the lower right corner of the panel. (b) Intensity-weighted velocity map of C2 in regions where $N'_{\text{HI}} \geq 10^{20} \text{ cm}^{-2}$. The grayscale spans 585–600 km s$^{-1}$ on a linear scale, as indicated by the wedge at the top of the plot. Contours are at (583, 586, 592, 595, and 598) km s$^{-1}$.

(A color version of this figure is available in the online journal.)

Figure 8. Integrated spectral profiles of C1 ($\delta V' = 31.0 \text{ km s}^{-1}$; solid lines and circles) and C2 ($\delta V' = 20.7 \text{ km s}^{-1}$; dashed lines and triangles) from the VLA observations.

(A color version of this figure is available in the online journal.)

Figure 9. Position–velocity plot of the HI distribution in C1 along (a) $PA'_{\text{HI}} = 36^\circ$, the position angle at which the maximum linear extent $a'_{\text{HI}}$ was measured (see Table 4), (b) the axis perpendicular to $PA'_{\text{HI}}$. In both panels, the position axis increases with increasing R.A., and its origin corresponds to $\alpha' = 12h30m 24.0s, \delta' = +9^\circ27'41''$ (J2000). Contours are at $0.35 \times (−2, −1, 2(2 \sigma'_m), 3, 4, 5, \text{and} 6) \text{ mJy beam}^{-1}$; negative contours are represented with dashed lines.

(A color version of this figure is available in the online journal.)

$cz'_0 = 486 \text{ km s}^{-1}$. The apparent “clumpiness” of the detected emission down to the synthesized beam width of $\sim 22''$ (1.8 kpc) is not a deconvolution artifact, and suggests that the cloud exhibits structure on even smaller scales. The box in Figure 6(a) encloses a faint, uncataloged optical feature that is coincident with a high $N'_{\text{HI}}$ peak in C1; we discuss the implications of an association between these optical and HI sources in Section 6. Figures 6(b) and 9 show that the cloud has no coherent velocity structure.

Figures 4 and 6 illustrate that there is very good agreement between the centroid of the C1 emission detected by ALFALFA and that detected by the VLA. The global properties of C1 measured from the VLA data also correspond well with those obtained from the ALFALFA data, although less HI flux is detected in the former ($F'_c/F_c = 86\% \pm 4\%$; Tables 2 and 4). If this “missing” flux is uniformly distributed over a circular region at least 1.5'' across, it would escape detection at the $3\sigma_m$ level in an optimally smoothed frequency channel of the VLA data. If it is contained in a coherent structure, we expect it to be kinematically coincident with the arc in Figure 6 since $cz'_0 - cz''_0 \sim 0$.

Cloud C2: Figures 5 and 7 illustrate that C2 has a markedly different HI morphology from C1. The emission in each channel of the VLA observations is barely resolved both spatially and spectrally, with the bulk of the emission in an unresolved feature at $a' = 12^h31^m18^s, \delta' = +9^\circ29'30''$ (J2000) in the
corresponds to a maximum extent $a_{HI}$ measured (see Table 4). The position axis increases with increasing RA, and its origin corresponds to $\alpha' = 12^h 31^m 19.2^s = +9^\circ 29' 01''$ (J2000). Contours are at $0.46 \times (-3, -2, 2 (2\sigma_c'), 3, 4, 5, \text{and} 6)\text{ mJy beam}^{-1}$; negative contours are represented with dashed lines.

$c\delta_c = 585 \text{ km s}^{-1} \text{ channel}$. The total intensity map of C2 in Figure 7(a) consists of two clumps: that to the northwest results from the brightest H1 feature at $c\delta_c = 585 \text{ km s}^{-1}$, and that to the southeast results from emission distributed over $585 \text{ km s}^{-1} < c\delta_c < 625 \text{ km s}^{-1}$. Figures 7(b) and 9 indicate that there is a ~15 km s$^{-1}$ gradient in the velocity field of C2. Given the poor sensitivity and resolution of the VLA data across the detection, it remains unclear whether or not this gradient stems from coherent internal motions.

A comparison between the integrated properties of C2 derived from the ALFALFA and VLA observations suggests that a small but statistically significant amount of H1 in this source has not been detected by the VLA ($M_{H1} - M_{HI} = [1.0 \pm 0.5] \times 10^5 M_{\odot}$; Tables 2 and 4). There are few direct constraints on the morphology of the missing gas. However, given the gradient in the C2 velocity field (Figure 7(b)), the quantities $cz_c - cz_c' = (10 \pm 5) \text{ km s}^{-1}$ and $W50 - W50' = (18 \pm 9) \text{ km s}^{-1}$ are consistent with a kinematically coherent extension to the southeast beyond that detected at $cz_c = 626 \text{ km s}^{-1}$ in Figure 5.

The star in Figures 5 and 7(a) denotes the optical location of VCC 1357 (Binggeli et al. 1985). The VLA observations therefore confirm the offset between this source and C2 suggested by the ALFALFA data (Section 2.2). It is thus clear that if C2 is associated with VCC 1357, then the gas in this system is displaced by ~2' (10 kpc in projection, or ~10 optical diameters; Binggeli et al. 1993) from the stars. We discuss the implications of an association between these H1 and optical features in Section 5.

### 3.3. Non-Detections in the VLA Follow-Up Data

While the complex clouds C4 and C5 fall within the field-of-view and bandpass of our VLA observations, they are not detected in the resulting dataset. This is not surprising given their projected distances of 11.2 and 12.5 from the pointing center in Table 4. Given the integrated spectral profile shapes and centroids of these clouds in the ALFALFA survey data (Table 2), we expect their emission to fall below the $3\sigma_c$ detection limit in the VLA data cube if they are smoothly distributed over a circular region with a diameter $\geq 1'$. The VLA nondetections therefore provide little insight into the morphologies and kinematics of C4 and C5.

### 4. CO(3–2) OBSERVATIONS

An exploratory observation of the CO(3–2) emission line consisting of a single pointing (R.A.(J2000) = 12h 30m 27s, decl. (J2000) = +9° 28' 34''.5) was carried out with the APEX Telescope (Güsten et al. 2006) located in the Chajnantor Plateau in northern Chile. This pointing was chosen because corresponds to the peak of the H1 emission in the VLA map. The observations took place during the night of 2008 January 1, using the the 345 GHz DSB heterodyne receiver APEX-2A. The beam-size (FWHM) of the APEX 12 m telescope is 18'' at 345 GHz. The receiver was tuned to CO(3–2) at $V_{\text{lsr}} = 490 \text{ km s}^{-1}$, with a total bandwidth of 1550 km s$^{-1}$ and spectral resolution of 0.8 km s$^{-1}$. Observations were performed with an atmospheric opacity at 220 GHz of 0.34, with a mean PWV ~ 2 mm yielding to a $T_{\text{sys}}(\text{DSB}) = 370 \text{ K}$. Pointing using Saturn as reference was regularly performed and was better than 2''.

The total on-source integration time was 36 minutes, reaching an rms of 48 mK with a spectral resolution of 0.9 km s$^{-1}$. The antenna efficiency was estimated at 70%.

Data reduction and analysis were performed using the CLASS package from the GILDAS software (Pety 2005). Reduction consisted of baseline subtraction and the integration of the individual scans. The adjacent channels were re-binned to a velocity resolution of 22.9 km s$^{-1}$, leading to a rms of 12.9 mK in $T_{\text{mb}}$. No clear detection was found.

These exploratory CO(3–2) observations allow us to place an upper limit to the mass in molecular form in C1. In order to estimate a 3$\sigma$ upper limit, we assume an expected line width of 50 km s$^{-1}$, yielding to a $T_{\text{CO}(3-2)} = 1.95 \text{ K km s}^{-1}$. We assume a conversion "X" factor between the CO(1–0) line and the molecular hydrogen column density $N_{\text{H2}}$. 2.8 x 10$^{20}$ cm$^{-2}$ (km s$^{-1}$)$^{-1}$ (Bloomen et al. 1986). We also adopted a CO(3–2)/CO(1–0) integrated line intensity ratio of 0.4 which is the typical value of the Galactic disk (Sanders et al. 1993). These values yield a H2 column density limit for the observation of $N_{\text{H2}} < 1.3 \times 10^{21}$ cm$^{-2}$, averaged over a beam of 18''. At a distance of 16.7 Mpc, this column density over a 1' diameter is equivalent to a molecular hydrogen upper mass limit of $M_{\text{H2}} < 4.0 \times 10^5 M_{\odot}$, which is comparable to the H1 mass (see Table 2). Allowing for uncertainties in the value of the X factor, the metallicity of the cloud gas, and the CO(3–2)/CO(1–0) integrated line ratio, we can conclude that the gas mass in the cloud C1 is unlikely to be dominated by the molecular component.

### 5. THE ENVIRONMENT OF THE CLOUD COMPLEX

The optical feature of unknown redshift appearing in the field of C1 and discussed in Section 3.2 appears to be just above the SDSS g-band detection limit. If the feature is approximately ~10'' across, then its g-band luminosity at the Virgo distance would be $L_g \sim 10^6 L_{\odot}$. The stellar M/L ratios models of Bell et al. (2003) give $M^*/L^* \sim 1.6$. If this feature is the optical counterpart of C1, then the stellar to H1 mass ratio is less than 0.01 and $M_{\text{HI}}/L_g > 170$. An analogous exercise for C2 and the putative counterpart VCC 1357 yields a stellar to H1 mass ratio of less than 0.05.

As for the possible optical counterparts of clouds C1 and C2, attempts to obtain optical redshifts were made in two occasions with the Palomar 5 m Hale telescope. The first time was unsuccessful due to limited sky transparency, the second due to lack of any discernible Hg emission or of any other measurable spectral signature. The possibility of an association between H1 and optical features remains open.

Figure 11 shows the Virgo Cluster X-ray emission in the vicinity of the H1 cloud complex (Snowden et al. 1995). The large X-ray emission regions are centered on M49 and M87,
Figure 11. Environment of the H\(_i\) cloud complex within the greater cluster area. The crossed circles indicate the five components of the complex discussed in this paper. The large plus (+) indicates the position of SBa galaxy NGC 4424 (cz\(_{\odot}\) = 476 km s\(^{-1}\)). The large X indicates the position of Sab galaxy NGC 4445 (cz\(_{\odot}\) = 354 km s\(^{-1}\)). The X-ray peaks are labeled indicating Virgo cluster galaxies M49 and M87 (Snowden et al. 1995). The symbols are not indicative of source sizes and are shown only for positional indication.

Near the projected location of the cloud complex, Völmer et al. (2001) estimate that the hot intracluster gas (ICM) density is \(n_{\text{icm}} \sim 10^{-4} \text{ cm}^{-3}\), while Shibata et al. (2001) have measured an ICM temperature of \(T_\text{B} = 0.235\) in units of \(10^8\) K.

Several galaxies are projected in the vicinity of the cloud complex. Figure 12 shows all cataloged objects within 1\(^\circ\) of C1 and with heliocentric velocities between 100 and 900 km s\(^{-1}\); galaxies detected in the 21 cm line are plotted with a circle of area proportional to the H\(_i\) mass; galaxies not detected in the ALFALFA with redshift information from other sources are plotted with crosses, most of which are early-type systems. It is assumed that all galaxies are located at the distance of the Virgo cluster. Note that the velocities of the H\(_i\) clouds range between 480 and 607 km s\(^{-1}\), i.e. if they are part of the Virgo cluster their line-of-sight velocity with respect to the cluster reference frame is directed toward us, as the heliocentric velocity of the cluster is 1150 km s\(^{-1}\) (Huchra 1988). Under the assumption that the clouds originated in the disk of a galaxy moving at high speed through the cluster, the velocity of the parent galaxy should also be incoming in the cluster reference frame, and most likely doing so at a larger velocity than the clouds themselves, as the latter would be decelerated by ram pressure after stripping. In the heliocentric reference frame, the parent galaxy should then have a lower velocity than those in the cloud complex. Two objects satisfy that condition: NGC 4424 and NGC 4445. Their locations are indicated by a plus sign (NGC 4424) and X symbol (NGC 4445) in Figure 11. In addition, as we discuss below, they are also extremely gas deficient for their size, which is evidence that they have been stripped within the last passage through the cluster.

The SBa galaxy NGC 4424 (also known as UGC 7561 and VCC 9079) is located at \(\alpha = 12^h 27^m 11^s 6, \delta = +09^\circ 25' 14''\) (J2000). This places NGC 4424 at a projected distance of 236 kpc from the cloud center, and 900 kpc from M87. This peculiar galaxy is at a velocity (cz\(_{\odot}\) = 437 km s\(^{-1}\)), near that of the main cloud. The angular size of the stellar component, 3.6' \(\times\) 1.8', translates to a linear size of 17' \(\times\) 9 kpc at the Virgo distance. A detailed study by Cortes et al. (2006) characterizes it as having disturbed morphology; they also suggest that CO observations are indicative of noncircular gas motions and discuss convincingly the vulnerability of the galaxy to ram pressure stripping.
pressure stripping (see also Kenney et al. 1996). NGC 4424 has a H\textsubscript{i} mass of \(2.5 \times 10^8\) \(M_\odot\) and estimations of H\textsubscript{i} deficiency values have been reported between 0.75 (Chung et al. 2007) and 1.09 (Helou et al. 1984). Those figures indicate that NGC 4424 has lost between 80\% and 90\% of its H\textsubscript{i} gas. Chung et al. (2007) noted that NGC 4424 exhibits a one-sided tail extending to the southeast, which is also detected by ALFALFA, and that the H\textsubscript{i} disk is truncated at a radius smaller than that of the stellar component of the galaxy. The direction of the tail shows the southeast to northwest direction of motion for NGC 4424; this motion is not compatible with the position of the cloud complex.

NGC 4445 (also known as UGC 7587 and VCC 1086) is an edge on spiral, possibly of type Sab, located at \(\alpha = 12^h28^m15^s, \delta = +09^\circ26^\prime11^\prime\) (2000). Its heliocentric radial velocity is \(c z_\odot = 354\) km s\(^{-1}\) and the H\textsubscript{i} mass \(5.5 \times 10^7\) \(M_\odot\) (Kent et al. 2008). Solanes et al. (2002) estimate its H\textsubscript{i} deficiency between 0.98 and 1.11, i.e. NGC 4445 has lost about between 90\% and 93\% of its H\textsubscript{i} gas. With a major axis angular diameter of 2\cretion{0}, its linear size is about 13 kpc. We are not aware of H\textsubscript{i} synthesis data of this object; none are found in the VLA data archive.

6. DISCUSSION

One possibility that merits consideration is that the clouds are gravitationally bound structures, embedded in their own dark matter halos. If an H\textsubscript{i} cloud is gravitationally bound, its total dynamical mass within the H\textsubscript{i} radius can be computed from Equation (3), assuming spherical symmetry. Such mass is \(2.3 \times 10^9\) \(M_\odot\) for C1 and \(0.5 \times 10^9\) \(M_\odot\) for C2 as calculated from the aperture synthesis measurements. The density of such objects would be \(1.4 \times 10^{-25}\) g cm\(^{-3}\) for C1 and \(1.0 \times 10^{-25}\) g cm\(^{-3}\) for C2. These densities can be compared to the critical density, \(\rho_{\text{crit}} = (1.9 \times 10^{-29}\) g cm\(^{-3}\) \(h^2\), where \(h = 0.7\). Were dark matter to provide the gravitational binding and to extend well beyond the visible, baryonic component, the total halo mass of, e.g., C1 would exceed \(10^{10}\) \(M_\odot\). In that case, it would be surprising that the VLA data do not exhibit any trace of ordered motions in the gas, nor does the visible matter show any degree of central concentration, thus violating the mass–concentration relation for halos. A similar issue can be raised for the whole cloud complex. If bound by self-gravity, its total dynamical mass would be of order of \(10^{11}\) \(M_\odot\) and its mean density \(2.1 \times 10^{-27}\) g cm\(^{-3}\). Again, the cloud complex shows no ordered motions. The possibility that the clouds in the complex are a group of optically dark galaxies embedded in their own dark matter halo appears relatively implausible.

For a purely gravitational event, we may expect stream-like topology in the removed gas, which is not observed. High speed galaxy–galaxy encounters tend to produce relatively small damage in terms of gas mass loss by the victim, albeit spectacular in spatial extent as in the case of NGC 4254/VirgoHI 21. For NGC 4424 and NGC 4445, the damage would have been quite substantial (more H\textsubscript{i} is seen in the cloud complex than in either of the galaxies themselves) and the topology of the remnant is not particularly streamlike. These are not however very strong arguments and the possible origin through a high speed close encounter cannot be excluded.

Ram pressure stripping is very likely if the galaxy’s orbit takes it deep in the cluster potential well, and can result in severe gas depletion from its outer disk (Cortes et al. 2006). With a radial velocity differing from the systemic velocity of the cluster by 700 km s\(^{-1}\) and a projected location half way between M87 and M49, the likelihood that ram pressure is currently very effective is marginal; it could however have been far more effective a few \(10^9\) years ago, if the orbit dipped closer to the cluster center, independently on whether or not an encounter or merger took place. As we will see, that likelihood is even higher for NGC 4445.

6.1. Orbital Motion Through the ICM: a Simple Simulation

We consider the motion of a galaxy as it dips into the ICM on a parabolic orbit of pericenter distance \(r_p\). Parametrized by the azimuthal angle \(\phi\), as illustrated in Figure 13, the distance
of the galaxy from the focal point (M87) is

\[ r = \frac{2r_p}{1 + \cos \phi} \]

while the orbital escape velocity is

\[ v_g = \sqrt{\frac{2GM_{clu}}{r}}, \]

where \( M_{clu} \) is the cluster mass. For simplicity, we assume the cluster mass is concentrated in M87 and equal to \( 10^{14} M_\odot \), rather than integrating the motion for a changing cluster mass within the variable \( r \), which is sufficient for our purposes. For the ICM density \( n_{icm} \) we assume the \( \beta \)–model (Schindler et al. 1999; Vollmer et al. 2001), given by

\[ n_{icm} = n_0 \left(1 + \frac{r^2}{r_{clus}^2}\right)^{-3\beta/2} \]

with a central density of \( n_0 = 0.04 \text{ cm}^{-3} \) and a core radius of \( r_{clus} = 21 \text{ kpc} \), appropriate for the SW sector of the cluster and \( r_{clus} = 13.4 \text{ kpc} \) for the cluster as a whole.

As the galaxy travels through the ICM, we assume the galactic gas is stripped at pericluster; from there on, we estimate the ram acceleration and integrate the growing separation \( \Delta r \) and \( \Delta v \) between the galaxy and clouds. Figure 14 shows the orbital parameters for pericluster distances of \( r_p = 400, 500, \) and \( 600 \text{ kpc} \). The best orbit in this simple exercise is fit with \( r_p \sim 500 \text{ kpc} \). In that scenario, a galaxy reaches a distance \( r = 1100 \text{ kpc} \) at 1.0 Gyr after pericluster passage. The velocity of the galaxy at \( r = 1100 \text{ kpc} \) is 1100 km s\(^{-1}\). Velocity \( \Delta v \) and spatial \( \Delta r \) separation values of 200 km s\(^{-1}\) and 300 kpc respectively are obtained from Figure 14. Corrections for the inclination along the line of sight for \( \theta \sim 45^\circ \) give values of \( \Delta r \sim 140 \text{ kpc} \) and \( \Delta v \sim 200 \text{ km s}^{-1} \). These numbers are in general agreement with the observed values.

### 6.2. Possible Formation Mechanisms

We can now consider two possible scenarios of cloud formation as the galaxy moves through the cluster: (1) removal by ram pressure and (2) a high speed tidal interaction of the type responsible for VirgoHI21 (Duc & Bournaud 2008; Haynes et al. 2007).

Ram pressure stripping will occur when the ram pressure arising from the motion of the galaxy at velocity \( v_{gal, 3d} \) with respect to the intracluster medium of number density \( n_{icm} \), \( n_{icm} m_p v_{gal, 3d}^2 \) (where \( m_p \) is the proton mass), exceeds the restoring gravitational force that binds the gas to the galaxy: \( 2\pi G \Sigma_{ism} \Sigma_d \), where \( \Sigma_{ism} \) is the gas surface density of the galactic disk and \( \Sigma_d \) is the total surface mass density of the disk. This condition can be rewritten as

\[ \left( \frac{n_{icm}}{10^{-3} \text{ cm}^{-3}} \right) \left( \frac{v_{gal, 3d}}{10^3 \text{ km s}^{-1}} \right)^2 \geq 11 \left( \frac{M_d}{10^{11} M_\odot} \right)^{-2} \left( \frac{R_{gal}}{10 \text{ kpc}} \right)^{-4} \times \left( \frac{M_{ism}}{0.1 M_d} \right), \]

where \( M_d \) and \( M_{ism} \) are now the total disk and gas masses within the radius \( R_{gal} \).

At the location of the cloud complex, some 845 kpc from M87, the density of the intracluster gas (ICM) is significantly lower than near the center of the cluster. For a \( \beta \)–model
from the cluster core of mass $M$ and moving at a velocity $v$ relative to the cluster.

(Equation (6)) at the present projected distance of the clouds from M87, $n_{icm} \sim 10^{-4}$ cm$^{-3}$. In the case of NGC 4424, $v_{gal,3d} \simeq 700/\cos \theta$ km s$^{-1}$, where $\theta$ is the angle between the line of sight and the galaxy velocity vector. We estimate a disk mass enclosed within $R_{gal} \simeq 10$ kpc of about $10^{10} M_\odot$ (a generous estimate, since the total velocity width of the H$\text{I}$ emission of the galaxy is 61 km s$^{-1}$(Kent et al. 2008) and the inclination of the disk, albeit unknown, is unlikely to be smaller than 45°) and assume $M_{\text{in}}/0.1 M_d \sim 1$. With those numbers, the ram pressure term roughly matches the restoring force at the larger galactocentric radii. Chung et al. (2007) also compute ram pressure effects in the range between $125 < n_{icm} v_{gal}^2 < 175$ cm$^{-3}$ (km s$^{-1}$)$^2$ and a restoring force range between $40 < \Sigma_{icm} v_{rot}^2 / R_{gal} < 475$ cm$^{-3}$ (km s$^{-1}$)$^2$ for NGC 4424.

In the case of NGC 4445, $v_{gal,3d} \simeq 800/\cos \theta$ km s$^{-1}$. The radial extent of the H$\text{I}$ disk is currently unknown, but we can estimate the ram pressure and the restoring force at $R_{gal} \simeq 6$ kpc, as well as its disk mass from a rotational velocity of 107 km s$^{-1}$, from the measured velocity full width of the H$\text{I}$ line of 213 km s$^{-1}$. Again, the ram pressure term is comparable with the restoring force at the galactocentric radii at which most of the H$\text{I}$ would be expected to be found in an unperturbed disk.

It is interesting to point out that NGC 4522, a very clear case of ram pressure stripping carefully studied by Kenney et al. (2004), is projected on the same region of the cluster (R.A. = 12h33m39s, decl. = 09°10′30″) albeit in a different velocity regime ($cz = 2307$ km s$^{-1}$). At the present location, Kenney et al. argue that the ICM density as described by the smooth $\beta$-model of Equation (6) is likely to be inadequate to explain the stripping. They invoke the possibility that the ICM may be locally denser than implied by the model.

**6.3. Timing Considerations**

Estimates of the tidal effects can be made by considering two nearby clouds in the vicinity of a cluster (Figure 15). The two clouds will disperse at a rate $\Delta v = g \Delta t$ under the gravitational tidal acceleration $g$ from the cluster potential, where $g$ is

$$g = \frac{2GM_{\text{cluster}}}{R_{\text{cluster}}^3},$$

where $M_{\text{cluster}}$ is the mass of the cluster within radius $R_{\text{cluster}}$ and $\Delta t$ is the initial separation of the clouds. The timescale of the encounter can be taken as $\Delta t \sim R_{\text{cluster}}/v_{c,3d}$, where $v_{c,3d} = v_c/\cos \theta$ is the velocity of the cloud complex with respect to the cluster. Taking $\Delta v = g \Delta t$, we can write a simple relation for the separation rate of the two clouds

$$\Delta v \approx \frac{2GM_{\text{cluster}}}{R_{\text{cluster}}^2 v_{c,3d}}.$$  \hspace{1cm} (9)

Two clouds initially separated by 10 kpc, located 845 kpc from the center of the cluster of mass $10^{14} M_\odot$ moving at a velocity of $600/\cos \theta$ km s$^{-1}$ with respect to the cluster would roughly double their separation in a time comparable with the cluster crossing time. Tidal forces related to the cluster potential alone are unlikely to account for the spatial dispersion of the clouds in the complex, if they were stripped from a single galaxy.

The cloud complex is separated by $\Delta r \sim 235/\sin \theta$ kpc and by $\Delta v \sim 100/\cos \theta$ km s$^{-1}$ in velocity from NGC 4424; the corresponding numbers for NGC 4445 are respectively $\Delta r \sim 150/\sin \theta$ kpc $\Delta v \sim 200/\cos \theta$ km s$^{-1}$. This separation would increase from zero to the observed value over a time of order

$$\Delta t_{sep,4424} \sim 2.3 (\tan \theta)^{-1} \text{ Gyr}$$

for NGC 4424 and

$$\Delta t_{sep,4445} \sim 0.7 (\tan \theta)^{-1} \text{ Gyr}.$$  \hspace{1cm} (11)

for NGC 4445. For relatively large values of $\theta$, they can be comparable with the time it takes for the galaxy to cross the inner regions of the cluster $R_{\text{cluster}}/v_{gal,3d}$. Under constant acceleration, the time necessary to reach the observed values of $\Delta r$ and $\Delta v$ would be about twice $\Delta t_{sep}$ as computed above. Either of those assumptions are unrealistic if ram pressure acts upon the clouds, as they travel through an ICM of variable density. However, two preliminary conclusions can be made already: (1) if the clouds originated from NGC 4445 or NGC 4424, the stripping took place at least a few $10^9$ years ago; (2) simple kinematic timescales make NGC 4445 as a more palatable candidate as a parent galaxy than NGC 4424. In the following, we concentrate our discussion on the assumption that the clouds were stripped from NGC 4445, although we maintain the inferred relations parametrized form for easy application to NGC 4424. Next, we derive the acceleration due to ram pressure.

As a spherical cloud of radius $r_c$ travels through the ICM at speed $v_{c,3d} = v_c/\cos \theta$, the force acting on its surface can be written as the ram pressure times the area, given by

$$F = n_{icm} m_p v_{c,3d}^2 \pi r_c^2.$$  \hspace{1cm} (12)

The resulting acceleration due to ram pressure is

$$a_{mp} = \Delta v / \Delta t = \frac{\rho_{icm} v_{c,3d}^2 r_c^2 \eta}{M_{\text{H}}},$$

where the factor $\eta$ accounts for the fraction of gas in form other than H$\text{I}$ and $M_{\text{H}}$ is the H$\text{I}$ mass of the cloud. The acceleration
can then be written as
\[ a_{\text{tp}} = 2.5 \times 10^{-9} \eta \left( \frac{n_{\text{icm}}}{10^{-3} \text{cm}^{-3}} \right) \left( \frac{r_c}{\text{kpc}} \right)^2 \times \left( \frac{v_c,3d}{10^3 \text{km s}^{-1}} \right)^2 \left( \frac{M_{\text{H1}}}{10^8 M_\odot} \right)^{-1} \text{[cm s}^{-2}] \text{.} \]  

(14)

Once the gas is stripped, while the motion of the galaxy is relatively unimpeded by the ram pressure, the clouds fall behind, affected by the pressure and the galaxy. In order to accumulate a velocity difference from the galaxy Δv, at constant acceleration a, a time on order of \( \Delta t = \Delta v/a \) will be required, while in order to accumulate a separation \( \Delta r \), a time on order of \( \Delta t_e = (\Delta r/a)^{1/2} \) will be required:
\[ \Delta t_e = 1.3 \times 10^8 \text{ yr} \left( \frac{\Delta v}{10^2 \text{ km s}^{-1}} \right) A \cos \theta \]  

(15)
\[ \Delta t_r = 5.0 \times 10^8 \text{ yr} \left( \frac{\Delta r}{10^3 \text{ kpc}} \right)^{1/2} A^{1/2} \cos \theta \sin^{-1/2} \theta \]  

(16)

where
\[ A = \eta^{-1} \left( \frac{n_{\text{icm}}}{10^{-3} \text{cm}^{-3}} \right)^{-1} \left( \frac{v_c}{10^3 \text{ km s}^{-1}} \right)^{-2} \times \left( \frac{r_c}{\text{kpc}} \right)^{-2} \left( \frac{M_{\text{H1}}}{10^8 M_\odot} \right) \text{.} \]  

(17)

For cloud C1, \( M_{\text{H1}} = 1.6 \times 10^8 M_\odot \). The maximum radius out to which the VLA detects H\textsc{i} emission in C1 is about 1.3, which translates to 6.5 kpc at the Virgo cluster distance. However, the effective radius of the cloud is very likely smaller than 6.5 kpc. A cursory inspection of Figure 6 shows that only about 1/3 of the area subtended by the emission out to a 1' radius exceeds a column density of gas at half the peak level, which would yield an effective radius of order of 3 kpc. In addition, from the topology of the H\textsc{i} gas in our own ISM, it is found that while the majority of the H\textsc{i} emission arises in denser regions, those clouds’ volume filling factor is quite small. Such structure would be unresolved by the 22' (1.8 kpc) beam of the VLA observations. Values of order \( r_c = 2-4 \) kpc appear appropriate. The parameter \( \eta \), which accounts for the mass fraction of He and other than H\textsc{i} gas, should be in the range 0.4–0.7. Near the current location of the clouds, the ICM density is unlikely to exceed \( n_{\text{icm}} \approx 10^{-4} \text{ cm}^{-3} \), unless the ICM is very clumpy, as suggested by Kenney et al. (2004). As for the parameters specific for the galaxies, for NGC 4424 \( v_e = 700 \text{ km s}^{-1} \), \( \Delta r = 235 \text{ kpc} \) and \( \Delta v = 100 \text{ km s}^{-1} \), while for NGC 4445 \( v_e = 800 \text{ km s}^{-1} \), \( \Delta r = 150 \text{ kpc} \) and \( \Delta v = 200 \text{ km s}^{-1} \). Note that by imposing \( \Delta t_e \approx \Delta t_r \approx 2 \) we can obtain a constraint on the combination of physical parameters
\[ 0.26A^{1/2} \left( \frac{\Delta v}{10^2 \text{ km s}^{-1}} \right) \left( \frac{\Delta r}{10^2 \text{ kpc}} \right)^{1/2} \sin^{1/2} \theta = 1. \]  

(18)

As we discussed earlier, accumulation of distance and velocity offsets between clouds and parent galaxy, \( \Delta r \) and \( \Delta v \), at either constant rate or constant acceleration are used under outlined above, and do not take into account projection effects, which would account for the orientation of NGC 4445 and the clouds with respect to M87 at the cluster center. It is important to note that a connection between NGC 4445 and the cloud complex is somewhat ambiguous, especially when compared to other disrupted gas features like NGC 4388 which show a clear connection in the form of a tail.

### 6.4. Evaporation Timescale

According to our findings, if the clouds were stripped from a parent galaxy, most of the stripping took place a fair fraction of a Gyr ago. In that case, it is reasonable to investigate the survival of the clouds in the ICM. Differential ram pressure forces will lead to ablation and dilution of the gas clouds. In addition, upon removal of the galaxy, the cold gas can be heated by conduction by the intracluster gas and the gas mass of the cloud would thus be progressively reduced by evaporation, if (presumably absent) stellar mass loss does not replenish the gas. The evaporation rate in \( M_\odot \text{ yr}^{-1} \) can be written as (Cowie & Songaila 1977)
\[ \dot{M}_{\text{ev}} \approx 16\pi \mu m_p \kappa r_{\text{kpc}}/25k \]  

\[ \approx 35 T_8^{5/2} r_{\text{kpc}} (40 / \ln \Lambda) M_\odot \text{ yr}^{-1}, \]  

(19)

where \( \mu \) is the mean molecular weight, \( m_p \) the proton mass, \( \kappa \) the thermal conductivity, \( T_8 \) the intracluster gas temperature in units of 10^8 K, \( r_{\text{kpc}} \) the effective cloud radius in kpc (proportional to the square root of the area of the cloud exposed to the ICM), \( k \) the Boltzmann constant and \( \Lambda \) the Coulomb logarithm. For \( T_8 = 0.235 \) (Shibata et al. 2001) and 40/\ln \Lambda \sim 1, the evaporation timescale is
\[ t_{\text{ev}} = M_{\text{gas}}/\dot{M}_{\text{ev}} \geq 1.7 \times 10^9 r_{\text{kpc}}^{-1} \psi^{-1} \text{yr}, \]  

(20)

where \( \psi \leq 1 \) is a correction factor roughly proportional to the fraction of the time the cloud’s orbit—between the time the gas is removed from the disk and the time of observations—places it in a part of the ICM within which the conductivity coefficient yields the evaporation rate in Equation (19). This estimate is very uncertain due to the largely unknown geometry of the cloud, an exact knowledge of its orbit through the ICM, the unknown fraction of the gas in ionized form and the possible presence of magnetic fields, which would inhibit conduction across field lines. It is clear from Equation (20) that if the H\textsc{i} gas is stripped from the galaxy in a region deep enough in the cluster ICM, conduction can obliterates evidence of the cold gas on timescales of < 10^9 yr. However, the rate in Equation (20) is approximately valid only in vicinity of the cluster core. Away from the central and denser parts of the cluster conduction becomes decreasingly effective, due to the rapid increase of the mean free path of electrons and conduction becoming saturated: this is thought to take place a couple of cluster ICM core radii (~ 50 kpc) out from the center of the ICM distribution (Sarazin 1986). This is why in the simulation described in the preceding section, we have maintained the closest approach of the galaxy to M87, \( r_p \), at values greater than a few hundred kpc; the evaporation timescale remains higher than the kinematical ones and the clouds can be preserved.

### 7. SUMMARY

We have utilized datasets from the ALFALFA survey and follow-up observations with the VLA to obtain both single dish and aperture synthesis observations of a new H\textsc{i} cloud complex in the Virgo Cluster. The results of these observations are summarized as follows:

1. Five separate H\textsc{i} clouds in the ALFALFA survey have been discovered with radial velocities between \( cz_\odot < 500 \) and 600 \text{ km s}^{-1}. The complex subtends an angle of 35' (170 kpc), the individual cloud H\textsc{i} masses range from 0.48
to $1.7 \times 10^8 M_\odot$ and the overall $H_\text{i}$ mass of the complex is $5.1 \times 10^8 M_\odot$ at the distance of the Virgo cluster. The clouds’ velocity widths vary between 50 and 250 km s$^{-1}$. In the latter case, the wide spectrum is likely to be due to a blend of several poorly resolved clumps.

2. Several cluster galaxies are found in the vicinity of the cloud complex; the most likely candidates for association with the clouds are NGC 4424, a disturbed SBa with $cz_\text{L} = 437$ km s$^{-1}$ at a projected distance of 235 kpc from the center of the cloud complex, and NGC 4445, an edge on spiral at a projected distance of 150 kpc, with $cz_\text{L} = 354$ km s$^{-1}$. Both galaxies are extremely $H_\text{i}$ deficient, apparently having lost between 80% and 93% of their $H_\text{i}$ gas. The total $H_\text{i}$ mass of the cloud complex is equivalent to between 1/2 and 1/3 of the $H_\text{i}$ lost by NGC 4424 and about 4/5 of the $H_\text{i}$ lost by NGC 4445.

3. Two of the clouds in the complex (C1 ad C2) have been detected with the VLA. They have angular sizes of 2.7 and 1.5 respectively. The synthesis maps do not exhibit any degree of symmetry in the gas distribution or in the velocity field. Faint optical features are found in the vicinity of the two clouds. Lack of optical redshifts prevent us from establishing a physical association. If the optical features were associated with the two clouds, their $H_\text{i}$ mass to $g$-band luminosity ratios would be respectively $M_{H_\text{i}}/L_g \sim 170$ for C1 and $M_{H_\text{i}}/L_g \sim 30$ for C2, in solar units. A handle on the $H_\text{i}$ size allows estimates of the dynamical masses of the clouds, contained within the $H_\text{i}$ radius and under the hypothesis that they are self-gravitating. Those values are $2.3 \times 10^9 M_\odot$ for C1 and $0.3 \times 10^9 M_\odot$ for C2.

4. The possibility that the clouds constitute a group of primordial structures, embedded in their own dark matter halos, appears unlikely. A more plausible scenario is that the complex is material removed from a galaxy traveling through the cluster at high speed, such as NGC 4424 or NGC 4445. A ram pressure stripping event is preferred to a purely gravitational one.

5. A simulation of plausible orbital parameters for the putative parent galaxy was carried out showing that a nearly radial orbit that would take it to within 400 kpc from M87 would produce effects comparable to those observed. Nearest approach to M87 would have resulted ~ 1 Gyr ago, at which stripping of most of the gas is assumed to have taken place. The nearest approach to the cluster center would be approximately 500 kpc. At that distance from M87, thermal conduction would be ineffective at evaporating the clouds after removal from the parent galaxy. At pericluster passage, the velocity (not corrected for line-of-sight inclination) of the galaxy would be $1100$ km s$^{-1}$. The inclination of the orbital plane to the line of sight of the best-fit simulation would be approximately 45°.

6. Dynamical timescales, based on relative velocities and spatial displacements of the clouds from the putative parent galaxy, suggest that the most likely such parent is NGC 4445.

This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. Skyview was developed and maintained under NASA ADP Grant NAS5-32068 under the auspices of the High Energy Astrophysics Science Archive Research Center at the Goddard Space Flight Center Laboratory of NASA.
