Abstract

Objective To assess the efficacy of caudal epidural steroid or saline injection in chronic lumbar radiculopathy in the short (6 weeks), intermediate (12 weeks), and long term (52 weeks).

Design Multicentre, blinded, randomised controlled trial.

Setting Outpatient multidisciplinary back clinics of five Norwegian hospitals.

Participants Between October 2005 and February 2009, 461 patients assessed for inclusion (presenting with lumbar radiculopathy >12 weeks). 328 patients excluded for cauda equina syndrome, severe paresis, severe pain, previous spinal injection or surgery, deformity, pregnancy, ongoing breast feeding, warfarin therapy, ongoing treatment with non-steroidal anti-inflammatory drugs, body mass index >30, poorly controlled psychiatric conditions with possible secondary gain, and severe comorbidity.

Interventions Subcutaneous sham injections of 2 mL 0.9% saline, caudal epidural injections of 30 mL 0.9% saline, and caudal epidural injections of 40 mg triamcinolone acetonide in 29 mL 0.9% saline. Participants received two injections with a two week interval.

Main outcome measures Primary: Oswestry disability index scores. Secondary: European quality of life measure, visual analogue scale scores for low back pain and for leg pain.

Results Power calculations required the inclusion of 41 patients per group. We did not allocate 17 of 133 eligible patients because their symptoms improved before randomisation. All groups improved after the interventions, but we found no statistical or clinical differences between the groups over time. For the sham group (n=40), estimated change in the Oswestry disability index from the adjusted baseline value was −4.7 (95% confidence intervals −6.6 to −2.8) at 6 weeks, −11.4 (−6.3 to −14.5) at 12 weeks, and −14.3 (−10.0 to −18.7) at 52 weeks.

For the epidural saline intervention group (n=39) compared with the sham group, differences in primary outcome were −0.5 (−6.3 to 5.4) at 6 weeks, 1.4 (−4.5 to 7.2) at 12 weeks, and −1.9 (−6.0 to 4.3) at 52 weeks; for the epidural steroid group (n=37), corresponding differences were −2.9 (−8.7 to 3.0), 4.0 (−1.9 to 9.9), and 1.9 (−4.2 to 8.0). Analysis adjusted for duration of leg pain, back pain, and sick leave did not change this trend.

Conclusions Caudal epidural steroid or saline injections are not recommended for chronic lumbar radiculopathy.

Trial registration Current Controlled Trials ISRCTN No 12574253.

Introduction

Chronic lumbar radiculopathy is defined as a clinical syndrome of back and leg pain accompanied by sensory, reflex, or motor deficits in a nerve root distribution lasting for more than 12 weeks.1–4 The lifetime prevalence of lumbar radiculopathy has been reported to be 5.3% in men and 3.7% in women.5–6 Lumbar radiculopathy due to a prolapsed disc resolves spontaneously in 23–48% of patients, but up to 30% will still have pronounced symptoms after one year, 20% will be out of work, and 5–15% will undergo surgery.7,10 Epidural steroid injections for lumbar radiculopathy have been used since 1953.11 Along with mechanical compression of nerve roots, lumbar radiculopathy can be triggered by different proinflammatory chemical agents,12–15 causing ectopic neuron firing.16 Steroids injected into the epidural space or around the affected nerve root are thought to inhibit these inflammatory mediators. However, there is conflicting evidence for a potential
benefit of epidural steroid injections. Some studies have shown a moderate short-term benefit, whereas others have shown little difference between epidural steroid and placebo injections. Studies comparing epidural steroid injections with epidural saline or local anaesthetic injections have shown less benefit from steroids than those comparing epidural steroid injections with sham or soft tissue injections. Furthermore, recent studies have concluded that epidural local anaesthetic or saline alone could have a positive effect by itself.

At the one year follow-up after epidural steroid injection, improvement of pain and disability has been reported for 36% to 43% of the patients. However, this outcome does not differ greatly from the natural history of the disease. The true effect of epidural steroid injections might be to reduce radicular pain before natural recovery occurs. Despite the lack of evidence for long term efficacy, the use of epidural steroid injection in the United States increased from 553 to 2055 per 100 000 patients from 1994 to 2001. In the United Kingdom, epidural steroid injection for lumbar radiculopathy was one of the most common therapeutic spine injection procedures in 2002-03.

We aimed to assess the effects of causal epidural steroid and saline injections compared with subcutaneous sham injections in patients with chronic radiculopathy, by measuring improvements in physical function, health related quality of life, and pain at short term (6 weeks), intermediate term (12 weeks), and long term (52 weeks) follow-up.

Methods

We used a subcutaneous sham injection to control for the possible effect of a high volume saline injected into the epidural space, and we compared epidural steroid injections with epidural saline injections to clarify the effect of steroids.

Participants

We referred patients with lumbar radiculopathy from the catchment area of the University Hospital of North Norway, St Olavs University Hospital, Levanger Hospital, Nordland Hospital, and Buskerud Hospital (population 1 146 076). The general practitioners, neurosurgeons, orthopaedic surgeons, neurologists, manual physiotherapists, and chiropractors working in these areas were informed by letter about the trial. The inclusion criteria included unilateral lumbar radiculopathy lasting for more than 12 weeks. The intensity of the leg pain, radiating from the back to below the knee, had to be comparable or worse than the back pain. We assessed eligible patients aged between 20 and 60 years consecutively for inclusion and obtained written informed consent. The clinical examination followed a prepared study template to decide whether the patient had a lumbar radiculopathy and to determine the most probable nerve root affected. Trained neurologists or specialists in physical medicine and rehabilitation in cooperation with a physiotherapist undertook the inclusion examinations. We excluded 328 patients presenting with a cauda equina syndrome, severe paresis, severe pain, history of spinal injection or surgery, deformity, pregnancy, ongoing breast feeding, warfarin therapy, ongoing treatment with non-steroidal anti-inflammatory drugs, body mass index of more than 30, poorly controlled psychiatric conditions with possible secondary gain, or severe comorbidity. Twenty four (7%) excluded patients underwent back surgery.

Follow-up

A blinded physiotherapist and doctor followed up patients at 6, 12, and 52 weeks. Use of physiotherapy was recorded during follow-up, but was not routinely offered to the patients. During the study, surgeons independently assessed the need for surgical treatment among patients with increasing pain or paresis.
We used a global question on a four point Likert scale to measure the benefit of the intervention at each follow-up. The patients were asked: “What benefit of the treatment have you had?” The response alternatives were: “much”, “some”, “no benefit”, and “I am worse”. We recoded these variables into a dichotomous outcome with “much” and “some” benefit representing that the patients had benefited from the treatment.

**Intervention**
A standardised referral letter for the intervention contained information about the patient’s cardiac and pulmonary status, medication, and allergies, but did not include information about back pain and radiculopathy. There were three intervention groups. Group 1 received subcutaneous injection of 2 mL 0.9% saline, superficial to the sacral hiatus and not into the spinal canal. Group 2 received caudal epidural injections of 30 mL 0.9% saline. Group 3 received caudal epidural injections of 40 mg triamcinolone acetonide in 29 mL 0.9% saline. All three intervention groups received two injections with a two week interval; the second injection was cancelled if spontaneous recovery had occurred between inclusion and the first intervention.

An experienced anaesthesiologist gave the injections and followed a set template. Anatomical landmarks were used to identify the sacral hiatus. In addition, use of an ultrasound machine (Honda Diagnostic Scanner HS-2000 Cine, Honda Electronics Co) capable of examining musculoskeletal tissues with a 10 MHz real time linear array ultrasound transducer increased the precision of the injections.

**Blinding**
We ensured that the patients, outcome assessors, and care providers were blinded during the study period; they were all unaware of the randomisation and intervention given by the anaesthesiologists. The anaesthesiologist giving the injection was not blinded because inclusion of a subcutaneous sham group made this impossible. The injection products were concealed from the patients, and the anaesthesiologists were instructed not to discuss the injection procedure or the products used with the patients.

**Statistical analysis**
We did sample size calculations for a multicentre multilevel longitudinal model with repeated measurements on the primary continuous outcome variable, the Oswestry disability index. The study was powered to detect an assumed clinically significant difference between one of the two injection groups and the sham group of 10 points on average over time. Based on a standard deviation of 18, a significance level of 5%, a power of 80%, and a correlation coefficient of 0.6 between the three follow-up measurements, the number of patients in each intervention group needed to be 37. Adjusting for losses to follow-up and withdrawals from the study, we set the minimum number of patients to be included in each group to be 41.

The analyses for all outcome measures used all available data on an intention to treat basis. We analysed all patients according to the group to which they were allocated, regardless of crossovers, surgery, withdrawal from the study, or loss to follow-up. In the analysis of outcomes in patients who withdrew or were lost to follow-up, we used the available data in the mixed model analysis. We analysed data with Stata 11.0 (StataCorp) and SPSS 17.0 (SPSS Inc.). Descriptive statistics were presented as means with standard deviations, means with confidence intervals, or numbers with percentages. We assessed groups at baseline by analysis of variance for continuous variables and by Pearson $\chi^2$ tests for categorical variables.

We used linear mixed models to assess differences in time trends between the treatment groups for the primary and secondary outcome measures. We added time to the model as a categorical variable represented by dummy variables to analyse the differences between the groups at different time points. In all mixed model analyses, we made a crude adjustment for the baseline values of the particular outcome variable. In secondary analysis, we made additional adjustments for any duration of back pain, leg pain, and sick leave before inclusion. All tests were two sided using a significance level of 5%.

**Results**
Between October 2005 and February 2009, 461 patients were assessed for inclusion, and 133 were included in the study (48, University Hospital of North Norway; 20, Nordland Hospital; 26, Levanger Hospital; 27, St Olav’s University Hospital; 12, Buskerud Hospital). Of the 328 excluded patients, three exclusions (1%) were because of intraspinal pathology and eight (2%) because of psychiatric conditions. Seventeen patients did not undergo randomisation because their symptoms improved between assessment and randomisation (fig 1). Therefore, we included 116 (25%) patients in the intention to treat analysis.

After randomisation, we excluded another five patients because of spontaneous improvement before the first injection (fig 1). We analysed 37 patients in the caudal epidural steroid group, 39 in the caudal epidural saline group, and 40 in the sham group (fig 1). We followed up 109 patients at 6 weeks, 105 at 12 weeks, and 99 at 52 weeks (table 1). We did not record any crossovers between the treatment groups. The distribution between treatment groups within each hospital was roughly equal, and adjustment for hospital did not change these results (table 2). Table 3 shows baseline characteristics of the study population. We did not detect any significant differences between treatment groups, except for a significantly higher rate of the presence of ankle tendon reflex difference among patients in the caudal epidural saline group. The median interval between inclusion and randomisation to the first injection was 3 (range 0-17) weeks, and the median interval between the two injections was 3 (2-5) weeks. This variation was caused by logistical and patient related factors affected by long travelling distance in rural Norway. We did not detect any difference in median time interval between inclusion and randomisation between the groups. We registered no serious complications from the injections. Six (5%) patients experienced local pain during the first injection and declined the second injection, thereby discontinuing the intervention (fig 1). The treatment groups did not differ significantly for the primary and secondary outcomes. Figures 2-5 show the between group differences for the primary and secondary outcome variables from baseline to follow-up. For both the primary and secondary outcome measures at 6, 12, and 52 week follow-up, we did not see any significant differences between the epidural injection groups and the sham group. Furthermore, the observed differences were not clinically important. The estimated change in the Oswestry disability index from the adjusted baseline value for the sham group was $-4.7$ (95% confidence intervals $-0.6$ to $-8.8$) at 6 weeks follow-up, $-11.4$ ($-6.3$ to $-14.5$) at 12 weeks, and $-14.3$ ($-10.0$ to $-18.7$) at 52 weeks. The observed between group differences at 6, 12, and 52 week follow-up between the epidural injection groups and the sham group were not clinically important. These
results did not change after we adjusted for both the baseline scores and the duration of leg pain, low back pain, and sick leave (tables 4⇑ and 5⇑).

Ancillary analysis
Fear avoidance belief scores decreased significantly from baseline to the 52 week follow-up in all three groups (P<0.001) but did not differ significantly between the groups (table 6⇓). We did not find a significant reduction in the use of pain relief medication from baseline to the 6 week follow-up, nor did we record any significant difference between the intervention groups in the use of paracetamol (P=0.26), non-steroidal anti-inflammatory drugs (P=0.45), or morphine (P=0.70) (table 7⇑).

Between baseline and 52 week follow-up, we detected a significant reduction in patients receiving sickness benefit in the sham group (P=0.01) but not in either of the epidural injection groups. However, there were no significant differences between the groups (P=0.61). At the 52 week follow-up, 28 (28%) patients received sickness benefit: 7 (22%) in the sham group, 10 (30%) in the epidural saline group, and 11 (32%) in the epidural steroid group.

During follow-up, 41 (13%) patients had physiotherapy: 12 (11%) at 6 weeks, 18 (17%) at 12 weeks, and 11 (11%) at 52 weeks, with no significant differences between the groups (P=0.69). Fifteen (15%) patients had back surgery at the 52 week follow-up: one (1%) in the epidural steroid group, six (6%) in the epidural saline group, and eight (8%) in the sham group, with no significant differences between the groups (P=0.07).

At baseline, all patients had clinically verified lumbar radiculopathy (table 1). At 52 week follow-up, 27 (27%) patients still had a lumbar radiculopathy, with no significant differences seen between the groups (P=0.95). At 52 week follow-up, 49 (50%) patients stated that they had received “much” or “some” benefit from the treatment, with no significant differences seen between the groups (P=0.81).

Discussion
This randomised controlled trial compared causal epidural steroid or saline injections with subcutaneous sham injections. The results confirm the null hypothesis that treatment of chronic lumbar radiculopathy with causal epidural injection of steroids or isotonic saline has no clinically important effect. We did not find any significant differences between the treatment groups in need of physiotherapy or surgery and the patients receiving sickness benefit. We expected fear avoidance belief scores to be low at baseline and to fall during follow-up, because patients were informed about the favourable prognosis of the lumbar radiculopathy and were repeatedly encouraged to stay active.

Comparison with existing literature
There is conflicting evidence on whether epidural steroid injections are efficacious,61-64 and if so, what volume, composition, or concentration of injection is best.29 53 64-70 Two randomised studies found that transformaminal steroid injections, which deposit the medication directly over the affected nerve roots, are more effective than causal epidural steroid injections in the short term.63 71 We did not address this issue in our study. Four randomised placebo controlled trials published between 1971 and 2009 with at least 12 months’ follow-up, including between 23 and 183 participants, found no long term effect of causal epidural steroid injections.79 30 32 33 72 One study showed a positive effect of causal epidural steroid injection.73 However, the reported effect size (change in Oswestry disability index score of 8.1 points) was smaller than what is considered to be the minimal clinically significant difference.43

High volumes of epidural solutions have been thought to clear or dilute locally concentrated chemical irritants around the spinal nerve roots.22-27 In our study, the effect of a high volume, causal epidural saline injection did not differ from a sham injection. Our results suggest that the effect attributed to isotonic saline probably reflects the spontaneous, natural course of lumbar radiculopathy.73

Strengths and limitations
This multicentre randomised controlled study was designed to determine whether high volume, epidural saline injections alone or epidural saline injections in combination with epidural steroid could benefit patients with longstanding radiculopathy. The study population was homogeneous with low psychosocial strain. We carefully selected patients on the basis of clinical criteria and not on strict magnetic resonance imaging findings. This method accords with how epidural steroid injections are used in daily clinical practice, improving the external validity of our study. We used the causal epidural injection technique with ultrasound guiding to improve the precision. However, we did not use contrast to visualise where the medication spread. The use of large volumes (30 mL) for the epidural injections ensured sufficient spread of the medication, reducing the need for radiography during the injection procedure.

Our power calculation required inclusion of 41 patients in each group to detect a 10 point between group difference for the primary outcome measure. We did not reach this goal because of rapid improvement in 17 patients between inclusion and randomisation. Therefore, the study was slightly underpowered, with four patients missing from the epidural steroid group, two from the epidural saline group, and one from the sham group. However, the study showed no trend towards any group difference after 12 months. We therefore consider it highly unlikely that a larger study population would have affected the results. Furthermore, the patients in our study had longstanding symptoms of radiculopathy (range 26-57 weeks), and our results might not be as relevant for patients with radiculopathy of shorter duration.

Low efficacy, under-dosage, and a dilution effect due to the high volumes injected could have influenced the effect of the causal epidural steroid injection in our study. The most commonly used steroids for epidural injections are triamcinolone acetonide, betamethasone, and methylprednisolone. One study compared triamcinolone and betamethasone and favoured triamcinolone.74 When given in equivalent doses, the efficacy of these three steroids is generally considered to be comparable.27 In one study, researchers also used triamcinolone to compare the effect of lumbar epidural steroid injection with placebo.22 They gave three 80 mg injections over nine weeks (total dose 240 mg), whereas we used two 40 mg injections over two weeks (total dose 80 mg). The observed effects from the previous study did not differ from our results. It is therefore unlikely that we could have improved the treatment effects by using another steroid, or by increasing the dose of triamcinolone.73

We thank Jan Inge Letto, Anne Sofie Broback, Dag Grindheim, Robert Kouwenhoven, Fredrik Granviken, Franz Hintringer, Svetlana Rasic, Helge Hartman, Sigrun Randen, and Einar Vegå for doing the assessments; Olaf Sivertsen, Just Thoner, Jørgen Hansen, Gunnar Engesnes, Niels Becker, and Tarjei Rygnes for doing the epidural
injections; the Clinical Research Centre at the University Hospital of North Norway; Bjørn Odvar Eriksen, Inger Sperstad, May Greta Pedersen, Sameline Grimsgaard, Dag Granvoll, Aslauq Jacobsen, Rolf Salvesen, Dagfinn Thorsvik, Tormod Hagen, Bjorn Skogstad, Therese Norberg Hanvold, and all the patients who participated in this study; and Bjørn Aske of Medinor Norway for lending us the Honda Ultrasound machines.
