Abstract This paper presents an explicit mixed finite element formulation to address compressible and quasi-incompressible problems in elasticity and plasticity. This implies that the numerical solution only involves diagonal systems of equations. The formulation uses independent and equal interpolation of displacements and strains, stabilized by variational subscales. A displacement sub-scale is introduced in order to stabilize the mean-stress field. Compared to the standard irreducible formulation, the proposed mixed formulation yields improved strain and stress fields. The paper investigates the effect of this enhancement on the accuracy in problems involving strain softening and localization leading to failure, using low order finite elements with linear continuous strain and displacement fields ($P_1 P_1$ triangles in 2D and tetrahedra in 3D) in conjunction with associative frictional Mohr–Coulomb and Drucker–Prager plastic models. The performance of the strain/displacement formulation under compressible and nearly incompressible deformation patterns is assessed and compared to analytical solutions for plane stress and plane strain situations. Benchmark numerical examples show the capacity of the mixed formulation to predict correctly failure mechanisms with localized patterns of strain, virtually free from any dependence of the mesh directional bias. No auxiliary crack tracking technique is necessary.

Keywords Explicit mixed finite elements · Stabilization · Incompressibility · Plasticity · Strain softening · Strain localization · Mesh independence

1 Introduction

In computational solid mechanics it is common to use displacements as nodal unknowns and to calculate strains by differentiation of the interpolated displacement field. These so-called irreducible formulations are very effective in a wide range of engineering problems; however, in certain cases, they lead to unstable, locking or spuriously mesh dependent results.

For instance, the performance of standard low order irreducible finite elements is extremely poor in quasi-incompressible situations, both in elasticity and plasticity. This is due to volumetric locking that brings in overstiff behavior and mean-stress (pressure) oscillations that hamstring the stress field. There exists considerable literature proposing solutions to this problem. Using displacements $u$ as primary variables, the first proposals were based on reduced integration [1–3], and extended to the use of assumed deformation $u − p$ approaches were introduced in the 90’s and used thenceforth to address the incompressible limit [6–9]. The reason for using the pressure as independent variable is to gain control on it and ensure stability; this results in an overall satisfactory behavior of strains and stresses in quasi-incompressible situations.

Discrete irreducible formulations have also proved inadequate in strain localization induced by softening constitutive behavior. In this instance, unrealistic mesh dependent solutions are obtained, with the bane of failure mechanisms, peak loads and energy dissipation being grossly mispredicted. Like incompressibility, failure mechanics has been an active topic of research in the last 30 years, with alternative explanations and consequent proposals being advocated. The preferred schemes go from the introduction of localization limiters, regularized and non-local constitutive models
to the more recent phase-field simulations. In references [10–
13] mixed pressure–displacement $u - p$ finite element (FE) formulations, free from volumetric locking, were shown to
tackle problems involving isochoric $J^2$ plasticity with strain
softening and localization, obtaining non spuriously mesh
dependent results. In these works, deviatoric strains are cal-
culated by differentiation of the displacement field; hence,
the rate of convergence for the angular distortions is the same
as in the irreducible formulation. More recently, Cervera et
al. [14–16] introduced a mixed $\varepsilon - u$ strain/displacement FE
formulation and have applied it to address problems of strain
localization using compressible and incompressible plastic-
ity models [17,18]. The objective of such formulation is to
achieve a discrete scheme with enhanced stress accuracy. The
resulting FE formulation displays a global rate of conver-
gence on stresses higher than the corresponding irreducible
formulation. Such improvement of the convergence estimates
also applies at local level. And this characteristic proves to
be crucial in strain localization problems involving softening
materials.

In the previously referenced mixed FE element formula-
tions, linear interpolation spaces were used for all primary
variables, displacements and pressure/strain. Three field for-
mulations $\varepsilon - u - p$ have also been proposed for the
incompressible limit [19,20]. All these mixed schemes are
stabilized via the variational multi-scale method (VMS)
[5,21–24], and, specifically, the Orthogonal Subgrid Scales
method, in order to gain control of all the variables while cir-
cumventing the restrictiveness of the inf-sup compatibility
conditions on the choice of the interpolation spaces. Simi-
lar mixed approaches have been proposed using alternative
stabilization techniques, like SUPG [7,25–27] or FIC [24].

It is worth to emphasize that stabilization is a tech-
nical means that enforces stability of mixed formulations
when the selected interpolation spaces do not satisfy the
Ladyzhenskaya–Babuska–Brezzi condition (inf-sup condi-
tion). Selecting compatible interpolation spaces provides
stable results [28]. However, the LBB is very restrictive
and it is not generally satisfied. Therefore, two possibilities
exist: (a) to design specific interpolations for any given situ-
ation, or (b) to choose the interpolation spaces freely and
use a stabilization technique that guarantees stability and
consistency.

This understood, the enhanced accuracy of the mixed $\varepsilon - u$
strain/displacement FE formulation derives from the consid-
eration of the kinematic equation in weak form, rather than
in strong form, as in the irreducible formulation. Strains are
interpolated independently of the displacements, rather than
obtained from local discrete differentiation. For the linear
problem, this significant enhancement of the discrete kinem-
atics guarantees local convergence of the strain field in
quasi-singular situations. For non-linear problems, this local
convergence can only be expected, not guaranteed. However,
numerical evidence on the performance of the mixed formu-
lation in problems with strain localization shows that the
kinematical enhancement is crucial in achieving convergent
mesh independent results.

The mixed displacement-strain formulation involves a
larger number of degrees of freedom (dofs) per node than in
the irreducible approach, which results in weightier sys-
tem of equations to be solved. In reference [29], the authors
proposed an explicit $\varepsilon - u$ strain/displacement mixed finite
element formulation (MEX-FEM in the following) to address
dynamic geometrically nonlinear problems in solid mechan-
ics. It was shown there that combining the mixed formulation
with an explicit time integration scheme yields a completely
explicit mixed approach that is very cost effective, because
of two reasons. On the one hand, the nodal displacement and
the nodal strains can be solved separately, in an staggered
manner; on the other hand, only diagonal systems of equa-
tions need to be solved. This procedure shows the feasibility
of the mixed approach for addressing other problems in solid
mechanics.

Based on this, the objectives of the present work are
three-fold: (i) to extend the applicability of MEX-FEM
into the quasi-incompressible elastic regime, (ii) to extend
the applicability of MEX-FEM into the compressible and
quasi-incompressible plastic regime, (iii) to demonstrate
that an explicit mixed formulation can satisfactorily solve
quasi-static physically nonlinear problems involving strain
localization.

Inelastic plastic flow is a directional phenomenon. Assum-
ing associative plasticity, it occurs in the direction normal to
the yield surface. An additional objective of this work is to
investigate the performance of the proposed mixed formula-
lation in strain localization situations to assess its satisfactory
performance under directional inelastic behavior, without
spurious stress locking and without the need of auxiliary dis-
continuity tracking procedures.

The organization of this paper is as follows. In Sect.
2, the mixed approach is presented, including the concept
of subscales and the stabilization procedure. Specifically,
a displacement subscale is introduced to tackle quasi-
incompressible situations. Relevant aspects of the numerical
implementation are recalled. Section 3 presents the exten-
sion of the formulation to the elasto-plastic range. The Mohr–
Coulomb and Drucker–Prager plasticity models, selected as
target models, are introduced. Constitutive integration, the
return algorithm and some general aspects about the ori-
entation of the localization band are discussed. Section 4
presents selected numerical examples involving unstructured
and structured low order finite elements meshes (triangles in
2D and tetrahedra in 3D) with continuous linear strain and
displacement fields to assess the generality and robustness
of the proposed formulation. Section 5 closes the paper with
some conclusions.
2 Explicit mixed strain/displacement formulation

2.1 Mixed strong and weak forms

In solid mechanics, the strain field $\varepsilon$ may be taken as an independent variable (in 3D, the symmetric tensor $\varepsilon$ has six components, $\{\varepsilon_{xx}, \varepsilon_{yy}, \varepsilon_{zz}, \varepsilon_{xy}, \varepsilon_{yz}, \varepsilon_{xz}\}$), additionally to the displacement fields $u$ ($u = \{u_x, u_y, u_z\}$, in 3D).

In this case, the strong form of the problem, at continuous level, can be written as: find the displacement field $u$, its time derivatives (velocity $\dot{u}$ and acceleration $\ddot{u}$) and the strain field $\varepsilon$, given the body forces $b$, so that:

$$\nabla \cdot \sigma + b = \rho \ddot{u} \quad \text{in} \quad \Omega \tag{1}$$

$$\varepsilon - \nabla^\text{T} u = 0 \quad \text{in} \quad \Omega \tag{2}$$

where $\Omega \subset \mathbb{R}^{n_{dim}}$ is the volume occupied by the solid in the space of $n_{dim}$ dimensions, $\rho$ is the material density and $\sigma$ is the stress tensor, assumed to be expressed in terms of the strains $\sigma = \sigma(\varepsilon)$, via a non-linear constitutive relationship of the type $\sigma = C \varepsilon$, with $C = C(\varepsilon)$ being the (secant) non-linear constitutive tensor; see Sect. 3 for the application to plasticity models. Eq. (1) represents the balance of momentum and Eq. (2) is the kinematic equation.

Equations (1) and (2) must be satisfied for all times $t \in [0, T]$ of the time interval of interest. Additionally, the problem is subjected to appropriate Dirichlet and Neumann boundary conditions, applied respectively to the parts $\partial \Omega_\text{d}$ and $\partial \Omega_\text{n}$ of the boundary $\partial \Omega$, so that $\partial \Omega = \partial \Omega_\text{d} \cup \partial \Omega_\text{n}$ and $\partial \Omega_\text{n} \cap \partial \Omega_\text{d} = \emptyset$. Also, the variables $\varepsilon$, $u$ and the derivative $\dot{u}$ are subjected to initial conditions at $t = t_0$, so that, $\varepsilon|_{t=t_0} = \varepsilon_0$, $u|_{t=t_0} = u_0$ and $\dot{u}|_{t=t_0} = \dot{u}_0$.

Let $\omega \in \mathcal{V}$ and $\gamma \in \mathcal{T}$ be the test functions for the displacement and strain fields, respectively, $\mathcal{V}$ and $\mathcal{T}$ being the functional spaces for the admissible displacement and strain fields. Multiplying Eqs. (1) and (2) by the respective test functions and integrating by parts Eq. (1), the weak form of the problem reads:

$$\int_\Omega \nabla^\text{T} \omega : \sigma \, d\Omega + \int_\Omega \omega \cdot \rho \ddot{u} \, d\Omega = \int_{\partial \Omega_\text{d}} \omega \cdot \bar{t} \, d\Gamma + \int_{\partial \Omega} \omega \cdot \bar{b} \, d\Omega \quad \forall \omega \tag{3}$$

$$\int_\Omega \gamma \cdot \varepsilon \, d\Omega = \int_\Omega \gamma \cdot \nabla^\text{T} u \, d\Omega \quad \forall \gamma \tag{4}$$

where $\bar{t} = \sigma \cdot n$ are the tractions on the outward direction $n$ in $\partial \Omega_\text{d}$.

To obtain the semi-discrete form of the problem, a discrete displacement field $u_h$, its time derivatives ($\dot{u}_h$ and $\ddot{u}_h$) and a discrete strain field $\varepsilon_h$ are defined. The discrete counterpart of Eqs. (3) and (4) is then:

$$\int_\Omega \nabla^\text{T} \omega_h : \sigma_h \, d\Omega + \int_\Omega \omega_h \cdot \rho \ddot{u}_h \, d\Omega = \int_{\partial \Omega_\text{d}} \omega_h \cdot \bar{t} \, d\Gamma + \int_{\partial \Omega} \omega_h \cdot \bar{b} \, d\Omega \quad \forall \omega_h \tag{5}$$

$$\int_\Omega \gamma_h \cdot \varepsilon_h \, d\Omega = \int_\Omega \gamma_h \cdot \nabla^\text{T} u_h \, d\Omega \quad \forall \gamma_h \tag{6}$$

where now $\omega_h \in \mathcal{V}_h$ and $\gamma_h \in \mathcal{T}_h$ are test functions belonging to the finite element spaces $\mathcal{V}_h$ and $\mathcal{T}_h$, respectively. The Ladyzhenskaya–Babuska–Brezzi condition ($\text{inf-sup}$ condition) imposes severe restrictions on the choices of pairs of interpolation spaces that guarantee stability and, therefore, unicity of the solution \cite{30,31}. For this reason, the solution spaces cannot be chosen freely. Unfortunately, most of low order mixed finite elements, including the simple $P1-P1$ element, with equal order strain/displacement linear interpolation, do not satisfy the LBB condition. This violation manifests in spurious oscillations in the both the displacement and pressure fields that jeopardize the numerical solution. Conveniently, the restrictions posed by the LBB condition may be circumvented by means of stabilization techniques to provide the necessary stability to the discrete mixed variational form. In these stabilized finite element forms, some appropriately constructed terms are added to Eqs. (5) and (6); these terms are residual-based and vanish upon mesh refinement, so that the consistency of the formulation is not affected. More details are given in the next Section.

Additionally, as Eqs. (5) and (6) are discrete in space but continuous in time, a time discretization algorithm is required. In this work, an explicit central differences scheme is used.

2.2 Variational multiscale stabilization

The stabilization method used in this work belongs to the remarkably successful framework of the variational multiscale method (VMS) of Hughes and collaborators \cite{23}. The fundamental idea of the method is to distinguish two scales or resolution levels, a coarse scale, at mesh level, that can be solved by the finite element approximation and another, finer one, that cannot be captured by the mesh resolution, and that is called sub-scale. Accordingly, the approximation of the continuous strain and displacement fields must contain components from both the scale and the sub-scale:

$$\varepsilon = \varepsilon_h + \tilde{\varepsilon} \tag{7}$$

$$u = u_h + \tilde{u} \tag{8}$$

where $\varepsilon_h \in \mathcal{T}_h$ and $u_h \in \mathcal{V}_h$ are fields defined in the coarse finite element scale and $\tilde{\varepsilon} \in \mathcal{T}$ and $\tilde{u} \in \mathcal{V}$ are the corresponding subgrid scales. Subsequently, the velocities
are approximated as \( \mathbf{u} = \mathbf{u}_h + \mathbf{\tilde{u}} \) and the accelerations as \( \ddot{\mathbf{u}} = \ddot{\mathbf{u}}_h + \ddot{\mathbf{\tilde{u}}} \).

Some technical details may be omitted by considering that the subscale enhancements behave as bubble functions, vanishing on the elements boundaries. They can be viewed as a “high frequency” perturbation of the finite element field, which cannot be resolved in \( \mathcal{V}_h [14,21] \).

Introducing the test functions \( \mathbf{\tilde{\omega}} \in \mathcal{V} \) and \( \mathbf{\tilde{y}} \in \mathcal{T} \) in the corresponding subscale spaces, the interpolation spaces are now extended to \( \mathcal{V} \simeq \mathcal{V}_h \oplus \mathcal{V} \) and \( \mathcal{T} \simeq \mathcal{T}_h \oplus \mathcal{T} \), respectively. Each particular stabilized finite element method is characterized by its choice of the spaces \( \mathcal{V} \) and \( \mathcal{T} \). The classical Galerkin method is recovered for \( \mathcal{V} = \mathcal{T} = \{0\} \).

Assuming that the subscale is small compared to the grid scale, the constitutive model is considered to be driven by the later. The non-linear secant constitutive tensor is taken as \( C = C(\varepsilon) \simeq C(\varepsilon_h) \) [14,15], and the plastic strain rate as \( \dot{\varepsilon}_p = \dot{\varepsilon}_p(\sigma) \simeq \dot{\varepsilon}_p(\sigma_h) \), so that the stress tensor in Eq. (47) can be written as:

\[
\sigma(\varepsilon) = C(\varepsilon_h) : \varepsilon_h + C(\varepsilon_h) : \tilde{\varepsilon} = \sigma_h + \tilde{\sigma} \tag{9}
\]

Introducing the two-scale approximation (Eqs. (7)–(9) and their counterparts for the test functions) into Eqs. (3) and (4), each one of these unfold into two equations, one corresponding to each scale. The equation of balance of momentum, Eq. (3), yields:

\[
\int_{\Omega} \nabla^3 \omega_h : \sigma_h \, d\Omega + \int_{\Omega} \nabla^3 \omega_h : \tilde{\sigma} \, d\Omega + \int_{\Omega} \omega_h : \rho \left( \mathbf{\tilde{u}}_h + \mathbf{\tilde{u}} \right) \, d\Omega = F_{ext}(\omega_h) \quad \forall \omega_h \tag{10}
\]

\[
\int_{\Omega} \nabla^3 \tilde{\omega} : \sigma_h \, d\Omega + \int_{\Omega} \nabla^3 \tilde{\omega} : \tilde{\sigma} \, d\Omega + \int_{\Omega} \tilde{\omega} : \rho \left( \mathbf{\tilde{u}}_h + \mathbf{\tilde{u}} \right) \, d\Omega = F_{ext}(\tilde{\omega}) \quad \forall \tilde{\omega} \tag{11}
\]

where the terms due to the external forces \( F_{ext}(\omega) \) are:

\[
F_{ext}(\omega) = \int_{\partial \Omega} \mathbf{\omega} \cdot \mathbf{n} \, d\Gamma + \int_{\Omega} \mathbf{\omega} \cdot \mathbf{b} \, d\Omega \tag{12}
\]

Similarly, the kinematic equation, Eq. (4), yields:

\[
\int_{\Omega} \gamma_h \cdot \varepsilon_h \, d\Omega + \int_{\Omega} \gamma_h \cdot \tilde{\varepsilon} \, d\Omega = \int_{\Omega} \gamma_h \cdot \nabla^3 \mathbf{u}_h \, d\Omega - \int_{\Omega} \left( \nabla \cdot \gamma_h \right) \cdot \mathbf{\tilde{u}} \, d\Omega \quad \forall \gamma_h \tag{13}
\]

\[
\int_{\Omega} \tilde{\gamma} \cdot \varepsilon_h \, d\Omega + \int_{\Omega} \tilde{\gamma} \cdot \tilde{\varepsilon} \, d\Omega = \int_{\Omega} \tilde{\gamma} \cdot \nabla^3 \mathbf{u}_h \, d\Omega + \int_{\Omega} \tilde{\gamma} \cdot \nabla^3 \mathbf{\tilde{u}} \, d\Omega \quad \forall \tilde{\gamma} \tag{14}
\]

where integration by parts has been used in Eq. (13).

The part of the governing equations corresponding to the subscale, Eq. (11) for the balance of momentum and Eq. (14) for kinematic compatibility, cannot be solved in the finite element space, and so an approximation for the subscales is required. Grouping terms, these equations read:

\[
\int_{\Omega} \tilde{\omega} \cdot (\nabla \cdot (C : \tilde{\varepsilon})) \, d\Omega + \int_{\Omega} \tilde{\omega} \cdot \rho \mathbf{\tilde{u}} \, d\Omega = \int_{\Omega} \tilde{\omega} \cdot \mathbf{r}_{u,h} \, d\Omega \tag{15}
\]

\[
\int_{\Omega} \tilde{\gamma} \cdot \mathbf{\tilde{u}} \, d\Omega - \int_{\Omega} \tilde{\gamma} \cdot \nabla^3 \mathbf{\tilde{u}} \, d\Omega = \int_{\Omega} \tilde{\gamma} \cdot \mathbf{r}_{\varepsilon,h} \, d\Omega \tag{16}
\]

where the point-wise residuals corresponding to the finite element scale are introduced as:

\[
\mathbf{r}_{u,h} = \nabla \cdot \sigma + b - \rho \mathbf{\tilde{u}}_h \tag{17}
\]

\[
\mathbf{r}_{\varepsilon,h} = \nabla^3 \mathbf{u}_h - \varepsilon_h \tag{18}
\]

This system of equations for the subscales can be written as:

\[
\mathcal{P}_{\mathcal{V}} \left( \nabla \cdot C : \tilde{\varepsilon} + \rho \mathbf{\tilde{u}} \right) = \mathcal{P}_{\mathcal{V}} (\mathbf{r}_{u,h}) \tag{19}
\]

\[
\mathcal{P}_{\mathcal{T}} (\tilde{\varepsilon} - \nabla^3 \mathbf{\tilde{u}}) = \mathcal{P}_{\mathcal{T}} (\mathbf{r}_{\varepsilon,h}) \tag{20}
\]

where \( \mathcal{P}_{\mathcal{V}} (\cdot) \) and \( \mathcal{P}_{\mathcal{T}} (\cdot) \) are the \( L^2 \) projection operators onto the subscale spaces, \( \mathcal{V} \) and \( \mathcal{T} \), respectively, defined by the expressions:

\[
\int_{\Omega} \tilde{\omega} \cdot \mathcal{P}_{\mathcal{V}} (\cdot) \, d\Omega = \int_{\Omega} \tilde{\omega} \cdot (\cdot) \, d\Omega \tag{21}
\]

\[
\int_{\Omega} \tilde{\gamma} \cdot \mathcal{P}_{\mathcal{T}} (\cdot) \, d\Omega = \int_{\Omega} \tilde{\gamma} \cdot (\cdot) \, d\Omega \tag{22}
\]

The system (19)–(20) clearly relates the subscales with the projection of the discrete residuals corresponding to the finite element scale, and suggests constructing a residual-based approximation for them. For this purpose, it is necessary to approximate the spatial and time differential operators that appear in the variational statement in discrete form. Regarding the spatial derivatives, Fourier’s analysis of the problem for the subscales [21] shows that, within each element domain \( \Omega_e \), the following algebraic approximations can be used for their respective norms:

\[
\| \nabla \cdot C : \tilde{\varepsilon} \| \simeq \frac{\| C : \tilde{\varepsilon} \|}{c_1 h} \simeq \frac{\mu}{c_1 h} \simeq \frac{\mu}{c_1 h} \frac{\| \mathbf{u} \|}{L_0} = \frac{1}{\tau_u} \| \mathbf{u} \| \tag{23}
\]

and

\[
\| \nabla^3 \mathbf{u} - \varepsilon \| \simeq \frac{\| \mathbf{u} \|}{c_3 h} \simeq \frac{1}{c_3 h} \frac{L_0 \varepsilon}{c_4} - \varepsilon \simeq \left( \frac{L_0}{c_3 c_4 h} - 1 \right) \| \varepsilon \| = \frac{1}{\tau_e} \| \varepsilon \| \tag{24}
\]
where \(\tau_u\) and \(\tau_e\) are the stabilization parameters, given by

\[
\tau_u = \frac{h L_0}{\mu} \quad \text{and} \quad \tau_e = \frac{h}{L_0} \tag{25}
\]

where \(c_e > 0\) and \(c_u > 0\) are non-dimensional algorithmic constants, \(h\) is the element size, \(L_0\) is a characteristic length of the problem and \(\mu\) is the secant shear modulus; it has been assumed that \(L_0 \gg h\). Numerical evidence shows that the constants \(c_e\) and \(c_u\) are \(O(1)\) and can be chosen in the range [0.1, 10.0].

Regarding the approximation of the time derivative \(\ddot{u}\), let us consider a uniform partition of the time interval \([0,T]\) of size \(\Delta t\) is considered, so that time \(n\Delta t = t^n\). Using a central difference scheme, it is:

\[
\ddot{u} \approx \frac{1}{\Delta t^2} \left( u^{n+1} - 2u^n + u^{n-1} \right) \tag{26}
\]

Using the approximations (23)–(24) and (26) in Eqs. (19)–(20), the subscales at time \(n + 1\) are calculated as:

\[
\tilde{e}^{n+1} = \tau_e \mathcal{P}_L \left( e_{r,h}^{n+1} \right) \tag{27}
\]

\[
\tilde{u}^{n+1} = \frac{\tau_u}{1 + \tau_u \frac{\rho}{\Delta t^2}} \left( \mathcal{P}_\nu \left( r_{u,h}^{n} \right) + \frac{\rho}{\Delta t^2} \left( 2\tilde{u}^n - \tilde{u}^{n-1} \right) \right) \tag{28}
\]

For steady-state situations, when \(\ddot{u} = 0\), the quasi-static approximation \(\tilde{u} = \tau_u \mathcal{P}_\nu \left( r_{u,h} \right)\) is properly recovered.

Observe that the point-wise values of \(\tilde{e}\) and \(\tilde{u}\) are not used, and thus Eqs. (27)–(28) need not to be understood point-wise. This approximation for the subscales is substituted in the integral terms in Eqs. (10) and (13), in order to mimic the stabilizing effect of the exact subscales. This is why the stabilization method is termed variational multiscale method.

### 2.3 Orthogonal subscale stabilization

It is clear from Eqs. (27) and (28) that there exist multiple possibilities to approximate the subscales, as they can be chosen in any space complementary to the finite element space. To fully define the stabilization method and compute the subscales, the complementary spaces \(\mathcal{V}\) and \(\mathcal{T}\), and the corresponding projections \(\mathcal{P}_e\) and \(\mathcal{P}_u\), must be selected. The simplest possible projection is the identity \(I\). The procedure so defined is called algebraic sub-scales (ASGS) [32]. Residual based stabilization techniques such as ASGS do not introduce any consistency error, as the exact solution annihilates the added terms, so that the stabilized model converges to the solution of the problem in continuous format. Also, if designed properly, the convergence rate is not altered; that is, the subscale terms are appropriately dependent on the mesh size.

Alternatively, Codina proposed to take the subscale spaces \(\mathcal{V}\) and \(\mathcal{T}\) orthogonal to the finite element spaces \(\mathcal{V}_h\) and \(\mathcal{T}_h\). This is called the orthogonal sub-scales (OSS) method [21, 32, 33]. In the present case, this means that the strain and displacement spaces are approximated as \(\mathcal{T} \simeq \mathcal{T}_h \oplus \mathcal{T}_h^\perp\) and \(\mathcal{V} \simeq \mathcal{V}_h \oplus \mathcal{V}_h^\perp\), respectively. Constructing the subscales in the subspace orthogonal to the finite element subspace has several advantages over the many other possibilities. The main one is that it guarantees minimal numerical dissipation on the discrete solution, because it adds nothing to those components of the residual already belonging to the FE subspace. This maximizes accuracy for a given mesh. Additionally, in transient problems, the residual term corresponding to the time derivative belongs to the finite element space, \(\mathcal{P}_h(\rho \tilde{u}_h) = \rho \tilde{u}_h\), and therefore, its orthogonal projection is null. This means that the mass matrix remains unaltered by the stabilization method, maintaining its structure and symmetry. In this work we will make use of this method.

Let the orthogonal projection operator be \(\mathcal{P}_h^\perp(\cdot) = (\cdot) - \mathcal{P}_h(\cdot)\), where \(\mathcal{P}_h(\cdot)\) is the \(L^2\) projection onto the finite element space, or least square fitting. Let us assume that the body forces \(\mathbf{b}\) can be described completely in \(\mathcal{V}_h\), so that \(\mathcal{P}_h^\perp(\mathbf{b}) = 0\) [18, 20]. Using the orthogonal projection, the subscales \(\tilde{e}\) and \(\tilde{u}\) in Eqs. (27)–(28) become:

\[
\tilde{e}^{n+1} = \tau_e \left( \nabla e_{u,h}^{n+1} - \mathcal{P}_h \left( \nabla e_{u,h}^{n+1} \right) \right)
\]

\[
\tilde{u}^{n+1} = \frac{\tau_u}{1 + \tau_u \frac{\rho}{\Delta t^2}} \left( \nabla \cdot \sigma_{h} - \mathcal{P}_h \left( \nabla \cdot \sigma_{h} \right) + \frac{\rho}{\Delta t^2} \left( 2\tilde{u}^n - \tilde{u}^{n-1} \right) \right) \tag{30}
\]

being \(\tilde{e}_{h}^{n+1} = \mathcal{P}_h \left( \nabla \cdot e_{u,h}^{n+1} \right)\).

The residual in Eq. (17) may be split as \(\nabla \cdot \sigma = \nabla \cdot p_h + \nabla \cdot s_h\), being \(s_h\) the deviatoric stress tensor and \(p_h\) the mean stress. In quasi-incompressible situations, it has been found to be effective to use only the mean stress gradient \(\nabla p_h\) in the approximation for the displacement subscale [18]:

\[
\tilde{u}^{n+1} = \frac{\tau_u}{1 + \tau_u \frac{\rho}{\Delta t^2}} \left( \nabla p_h - \mathcal{P}_h \left( \nabla p_h \right) + \frac{\rho}{\Delta t^2} \left( 2\tilde{u}^n - \tilde{u}^{n-1} \right) \right) \tag{31}
\]

This alternative has three advantages: (i) it reduces the computational stencil, (ii) it allows more selective norms to be defined for stability control and (iii) it has proved advantageous in problems involving singular or quasi-singular points. This variant of split-OSS belongs to the family of the term-by-term stabilization methods; the introduced consistency error is of optimal order and the final convergence rate of the scheme is not altered.
2.4 Explicit stabilized mixed form

To obtain the explicit stabilized form of the problem defined by the equations to be solved in the finite element space, Eqs. (10) and (13), the former needs to be discretized in time. Doing this via an explicit time advancing scheme is a well-known procedure for the irreducible formulation. Reference [29] discusses the relative merits of doing this for the mixed formulation, that is, incorporating the solution of the weak form of the geometric equation into the time marching scheme. The resulting explicit mixed method is conditionally stable, but, compared with its irreducible counterpart: (i) it shows enhanced strain and stress accuracy and (ii) it does not require a reduced critical time step.

On the one hand, the balance of momentum Eq. (10) is recalled at time \( t^n \) as:

\[
\int_{\Omega} \nabla \cdot \mathbf{F}_n = C(\mathbf{\varepsilon}_h^n) : \left[ \mathbf{\varepsilon}_h^n + \tau_e (\nabla \cdot \mathbf{u}_h^n) \right] \, d\Omega \\
+ \int_{\Omega} \mathbf{\omega}_h \cdot \mathbf{\rho} \mathbf{\bar{u}}_h \, d\Omega = F_{ext}^n(\omega_h) \quad \forall \mathbf{w}_h
\]

(32)

where the stress and strain subgrid scales from Eqs. (9) and (29) and the orthogonality condition \( \int_{\Omega} \mathbf{\omega}_h \cdot \mathbf{\bar{u}}_h \, d\Omega = 0 \) have been used. On the other hand, the geometric Eq. (13) is recalled at time \( t^{n+1} \) as:

\[
\int_{\Omega} \mathbf{\gamma}_h \cdot \mathbf{\varepsilon}_h^{n+1} \, d\Omega = \int_{\Omega} \mathbf{\gamma}_h \cdot \nabla \mathbf{u}_h^{n+1} \, d\Omega \\
- \int_{\Omega} (\nabla \cdot \mathbf{\gamma}_h) \cdot \mathbf{\bar{u}}_h^{n+1} \, d\Omega \quad \forall \mathbf{\gamma}_h
\]

(33)

where now the orthogonality condition \( \int_{\Omega} \mathbf{\gamma}_h \cdot \mathbf{\bar{u}}_h \, d\Omega = 0 \) has been used. From this, the strains \( \mathbf{\varepsilon}_h^{n+1} \) are obtained as:

\[
\mathbf{\varepsilon}_h^{n+1} = \mathbf{P}_h \left[ \nabla \mathbf{u}_h^{n+1} - (\nabla \cdot \mathbf{\gamma}_h) \cdot \mathbf{\bar{u}}_h^{n+1} \right] \\
= \mathbf{\varepsilon}_h^{n+1} - \mathbf{P}_h \left[ (\nabla \cdot \mathbf{\gamma}_h) \cdot \mathbf{\bar{u}}_h^{n+1} \right]
\]

(34)

Substituting this into Eq. (32) and approximating \( \mathbf{\varepsilon}_h^n \approx \mathbf{\varepsilon}_h^n \):

\[
\int_{\Omega} \nabla \cdot \mathbf{\omega}_h : C(\mathbf{\varepsilon}_h^n) : \left[ (1 - \tau_e) \mathbf{\varepsilon}_h^n + \tau_e \nabla \mathbf{u}_h^n \right] \, d\Omega \\
+ \int_{\Omega} \mathbf{\omega}_h \cdot \mathbf{\rho} \mathbf{\bar{u}}_h \, d\Omega = F_{ext}^n(\omega_h) \quad \forall \mathbf{w}_h
\]

(35)

Now, grouping terms and introducing the stabilized strains \( \mathbf{\varepsilon}_h^{stab,n} = (1 - \tau_e) \mathbf{\varepsilon}_h^n + \tau_e \nabla \mathbf{u}_h^n \), the first term in Eq. (35) is identified as due to the internal forces:

\[
F_{int}^n(\omega_h) = \int_{\Omega} \nabla \cdot \mathbf{\omega}_h : \mathbf{\sigma}_n \, d\Omega \\
= \int_{\Omega} \nabla \cdot \mathbf{\omega}_h : C(\mathbf{\varepsilon}_h^n) : \mathbf{\varepsilon}_h^{stab,n} \, d\Omega
\]

(36)

This allows writing the equation of dynamic equilibrium at time \( t^n \) in the usual matrix/vector form:

\[
\mathbf{M} \ddot{\mathbf{U}}^n = \mathbf{F}_n^{ext} - \mathbf{F}_n^{int}
\]

(37)

where \( \mathbf{U}^n \) is the vector of nodal displacements and \( \mathbf{M} \) is the mass matrix, so that \( \mathbf{F}_n^{mass} = \mathbf{M} \ddot{\mathbf{U}}^n \) are the inertial forces, and \( \mathbf{F}_n^{ext} \) and \( \mathbf{F}_n^{int} \) are the external and internal force vectors derived from their variational counterparts, respectively.

Introducing the central finite difference scheme to discretize the second time derivative as:

\[
\ddot{\mathbf{U}}^n = \frac{1}{\Delta t^2} \left( \mathbf{U}_n^{n+1} - 2\mathbf{U}_n^n + \mathbf{U}_n^{n-1} \right)
\]

(38)

the nodal displacements are obtained as:

\[
\mathbf{U}_n^{n+1} = \left( 2\mathbf{U}_n^n - \mathbf{U}_n^{n-1} \right) + \Delta t^2 \mathbf{M}^{-1} \left( \mathbf{F}_n^{ext} - \mathbf{F}_n^{int} \right)
\]

(39)

This completes the definition of the explicit time marching procedure to solve the stabilized mixed strain/displacement problem. For each time step \( t^{n+1} \):

1. Evaluate the internal forces in previous time step \( \mathbf{F}_n^{int} \) using Eq. (36).
2. Evaluate nodal displacements \( \mathbf{U}_n^{n+1} \) using Eq. (39).
3. Evaluate the displacement subscale \( \mathbf{\bar{u}}_n^{n+1} \) using Eq. (30).
4. Evaluate strains \( \mathbf{\varepsilon}_h^{n+1} \) using Eq. (34).
5. Go to next step.

The procedure is analogous to the one used for the standard irreducible formulation, apart from the additional steps 3 and 4. Therefore, it can be easily implemented in any FE code. Furthermore, the additional steps only require operations at element and node level that can be performed in parallel.

The scheme requires the solution of two systems of equations: the one in step 2 to obtain \( \mathbf{U}_n^{n+1} \) and another one in step 4 to perform the projection in Eq. (34). Both procedures are inexpensive, as the corresponding system matrices are constructed as diagonal.

2.5 Damping

Viscous forces, that is, forces which are proportional to the velocities, are often introduced in computational solid mechanics. The main reason for this is to model the physical dissipative mechanisms that damps the dynamic structural response in truly transient situations. In some quasi-static cases, algorithmic artificial damping is applied to induce a pseudo-transient response to reach a steady-state solution. Also, numerical damping is often used in computational schemes to filter out spurious high frequencies that may pollute the numerical solution.
In the finite element grid scale, these forces are added to the equation of dynamic equilibrium at time \( t^n \), Eq. (37), so that:

\[
M \ddot{U}^n + D \dot{U}^n = F_{\text{ext}}^n - F_{\text{int}}^n
\]

(40)

where \( F_{\text{visc}}^n = D \dot{U}^n \) are the viscous forces, \( D \) being the damping matrix.

Making \( \ddot{U}^n = (U^n - U^{n-1})/\Delta t \), the nodal displacements at \( t^{n+1} \) are obtained as:

\[
U^{n+1} = M^{-1} \left[ (2M - \Delta t D)U^n - [M - \Delta t D]U^{n-1} + \Delta t^2 (F_{\text{ext}}^n - F_{\text{int}}^n) \right]
\]

(41)

Mass- and stiffness-proportional damping, normally referred to as Rayleigh’s damping, is commonly used in linear and nonlinear solid dynamic analysis, because of its computational benefits. In Rayleigh’s damping, the damping matrix is assumed to be proportional to the mass and stiffness matrices:

\[
D = \alpha M + \beta K
\]

(42)

where \( \alpha \) and \( \beta \) are damping coefficients. In order to preserve the efficiency of the explicit scheme, Rayleigh’s damping is introduced in the form:

\[
U^{n+1} = \left[ (2 - \alpha \Delta t)U^n - (1 - \alpha \Delta t)U^{n-1} + \Delta t^2 M^{-1} (F_{\text{ext}}^n - F_{\text{int}}^n - \beta K \dot{U}^n) \right]
\]

(43)

where the viscous force term \( \beta K \dot{U}^n \) can be evaluated element-by-element, without assembling a global stiffness matrix.

In the variational multiscale approach, mass proportional damping is also considered in the displacement subscale; using the time derivative \( \ddot{u}^n = (\ddot{u}^n - \ddot{u}^{n-1})/\Delta t \), leads to a modified Eq. (30) for the evolution of the subscale:

\[
\ddot{u}^{n+1} = \frac{\tau_u}{1 + \tau_u \rho/\Delta t^2} \left( \nabla p_h^n - \nabla p_h \right) + \rho/\Delta t^2 \left( 2 - \alpha \Delta t \right) \ddot{u}^n - (1 - \alpha \Delta t) \ddot{u}^{n-1}
\]

(44)

2.6 Computational implementation

Explicit time integration is effective if the mass matrix \( M \) in Eq. (39) is diagonal [34]. In this case, the computation of the nodal displacements in step 2 of the explicit scheme is trivial. The same applies to the projection matrix that appears to perform step 4. This is a mass-like matrix that may be constructed as diagonal. In this work, a closed Gauss-Lobatto quadrature and mass proportional damping are used to ensure that all the matrices computed are diagonal.

Consider a \( P1P1 \) 4-noded tetrahedral element with the same linear interpolation functions for strains and displacements. In the mixed formulation, strains are linear, and a 4-point quadrature rule, sampling at the element nodes is necessary to evaluate the internal forces. Therefore, the same close quadrature with sampling at the nodes is used for all integrals over the element domain \( \Omega_e \).

The test functions \( \omega_i \) in the displacements space and \( \gamma_i \) in the strains space coincide with the interpolation functions, conventionally written in matrix form as \( N_\kappa = [N_\kappa^1 N_\kappa^2 N_\kappa^3 N_\kappa^4] \), \( \kappa = u, \epsilon \). Displacements and strains are interpolated inside each element from the nodal values as:

\[
u_h = \sum_{i=1}^4 N_i^u u_i \quad \text{and} \quad \epsilon_h = \sum_{i=1}^4 N_i^\epsilon \Sigma^i
\]

being \( N_i^\epsilon = \text{diag}(N_i, N_i, N_i) \) the 3 × 3 diagonal submatrix for the displacement interpolation function, \( U^T = \{u^x_i, u^y_i, u^z_i\} \) the nodal displacements, \( N_i^\epsilon = \text{diag}(N_i, N_i, N_i, N_i, N_i, N_i) \) the 6 × 6 diagonal submatrix for the strain interpolation function, \( \Sigma^i = \{\epsilon^i_{xx, h}, \epsilon^i_{yy, h}, \epsilon^i_{zz, h}, \epsilon^i_{xy, h}, \epsilon^i_{xz, h}, \epsilon^i_{yz, h}\} \) the nodal strains, all at node \( i \).

Note also that the tensor \( \nabla \cdot \omega_i \) appearing, for instance, in Eq. (36), is the discrete symmetric gradient operator, usually noted as \( B_u \) in matrix form, with \( B_u = [B_1 B_2 B_3 B_4] \), where each submatrix \( B_i \) is:

\[
B_i = \begin{bmatrix}
\frac{\partial N_i}{\partial X} & 0 & 0 & \frac{\partial N_i}{\partial Y} & 0 & \frac{\partial N_i}{\partial Z} \\
0 & \frac{\partial N_i}{\partial Y} & 0 & \frac{\partial N_i}{\partial X} & 0 & \frac{\partial N_i}{\partial Z} \\
0 & 0 & \frac{\partial N_i}{\partial Z} & 0 & \frac{\partial N_i}{\partial X} & \frac{\partial N_i}{\partial Y}
\end{bmatrix}
\]

Similarly, the discrete divergence operator \( \nabla \cdot \gamma_i \) in Eq. (34) is written in matrix form as \( B_\gamma = [B_1^\gamma B_2^\gamma B_3^\gamma B_4^\gamma] \).

3 Plasticity models

3.1 Plasticity constitutive relation

In small strain plasticity, the total strain \( \epsilon \) can be split into its elastic \( \epsilon_e \) and plastic \( \epsilon_p \) components

\[
\epsilon = \epsilon_e + \epsilon_p
\]

(45)

so that the stress can be written as:

\[
\sigma = C_0 : (\epsilon - \epsilon_p) = C_0 : \epsilon_e
\]

(46)
where $C_0$ is the elastic isotropic constitutive tensor. The elasto-plastic problem is fully defined by specifying flow rules of the type $\dot{\varepsilon}_p = \dot{\varepsilon}_p(\sigma)$ for the plastic strain. The plastic strain is integrated in time using return mapping algorithms [35].

Alternatively, the stress can be expressed in secant form as [18]:

$$\sigma = [C_0 - \frac{C_0 : \varepsilon_p \otimes C_0 : \varepsilon_p}{\varepsilon : C_0 : \varepsilon_p}] : \varepsilon = C(\varepsilon) : \varepsilon \tag{47}$$

where $C = C(\varepsilon)$ is the secant constitutive tensor. This secant form of the constitutive equation, not frequent in plasticity, is formally introduced to show that standard plasticity fits in the rather general mixed strain–displacement framework described in Sect. 2. Observe that it is not used in the explicit algorithm. Note also that the secant constitutive tensor in Eq. (47) has all the expected symmetry properties.

### 3.2 Mohr–Coulomb and Drucker–Prager plasticity models

The Mohr–Coulomb (MC) criterion, and associated plasticity model, is used to describe the failure of frictional materials and geomaterials in general. The behavior of these materials is characterized by the dependence of the effective cohesion on the pressure. The plastic strains are the result of the relative sliding and friction between particles. According to the MC criterion, plastic flow occurs when a certain combination of shear stress $\tau$ and normal stress $\sigma_n$ reaches a critical value:

$$|\tau| = c - \sigma_n \tan \phi \tag{48}$$

being $c \geq 0$ the cohesion and $0 \leq \phi \leq \pi/2$ the internal friction angle. For $\phi = 0$ the MC model reduces to Tresca’s model. Strain localization occurs if cohesion decreases as plastic strain grows. The MC criterion is often written as:

$$\Phi (\tau, \sigma_n, c(\bar{\varepsilon}_p), \phi) = |\tau| - c(\bar{\varepsilon}_p) + \sigma_n \tan \phi = 0 \tag{49}$$

where $\bar{\varepsilon}_p$ is the equivalent plastic strain, a scalar measure of the plastic strain. The MC criterion can also be expressed in terms of the stress invariants or, more frequently, as six planes in the Haigh–Westergaard space of principal stresses, where they form the characteristic hexagonal pyramid of the MC model. One of such planes is given by:

$$\Phi_1 (\sigma_1, \sigma_3, c(\bar{\varepsilon}_p), \phi) = (\sigma_1 - \sigma_3) + (\sigma_1 + \sigma_3) \sin \phi - 2c(\bar{\varepsilon}_p) \cos \phi = 0 \tag{50}$$

where $\sigma_1 \geq \sigma_2 \geq \sigma_3$ are the principal stresses. Figure 1 depicts the MC pyramid in the HW space. Note that this is a multisurface criterion with the apex located on the hydrostatic axis, at $\sqrt{3}c\cot\phi$ from the origin.

The Drucker–Prager (DP) criterion was proposed as a smoothed version of the MC criterion. It is also considered as an extension of the von Mises model in which the pressure dependence is considered. In this model, plastic flow occurs when the second invariant of the deviatoric stress tensor $J_2 = \frac{1}{2}s : s$ and the hydrostatic pressure reach a critical combination:

$$\Phi (\sigma, c(\bar{\varepsilon}_p), \phi) = \sqrt{J_2(\sigma)} + \eta p - \zeta c(\bar{\varepsilon}_p) = 0 \tag{51}$$

The DP criterion, Fig. 2, appears in the HW space as a cone whose axis coincides with the hydrostatic axis. Note that for $\phi = 0$ the DP model reduces to von Mises incompressible model. The parameters $\eta$ and $\zeta$ are usually chosen to approximate the MC criterion in different ways. In plane strain situations, to predict the same limit loads as with MC, $\eta$ and $\zeta$ are taken as [36]:

$$\eta = \frac{3 \tan \phi}{\sqrt{9 + 12 \tan^2 \phi}} \quad \text{and} \quad \zeta = \frac{3}{\sqrt{9 + 12 \tan^2 \phi}} \tag{52}$$

### 3.3 Return mapping, multisurface plasticity and softening

At each time step, the constitutive model must be integrated to update the value of the plastic strains. To this end, implicit algorithms to ensure that the stress stays in the yield surface during plastic flow are often used. These are the so-called return mapping algorithms. In multisurface associate plasticity, Koiter’s rule is used to define the plastic flow and the equivalent plastic strain rate [35]:

$$\dot{\varepsilon}_p = \sum_{k=1}^{n_{act}} \dot{\lambda}_k \frac{\partial \Phi_k}{\partial \sigma} = \sum_{k=1}^{n_{act}} \dot{\lambda}_k m_k \tag{53}$$

$$\dot{\bar{\varepsilon}}_p = - \sum_{k=1}^{n_{act}} \dot{\lambda}_k \frac{\partial \Phi_k}{\partial c} \tag{54}$$

where $\dot{\lambda}_k$ are the plastic consistency parameters and $n_{act}$ is the number of active surfaces. The problem consists on determining $\varepsilon_p, \lambda_k$ and the active surfaces $j := \Phi_k \forall k \in \{1, 2, \ldots, n_{act}\}$. Also, the plastic consistency parameters must fulfill the Kuhn–Tucker conditions extended to multiple surfaces plasticity:

$$\dot{\lambda}_k \geq 0, \dot{\lambda}_k \Phi_k (\sigma, c(\bar{\varepsilon}_p)) \leq 0 \quad \text{and} \quad \dot{\lambda}_k \Phi_k (\sigma, c(\bar{\varepsilon}_p)) = 0 \tag{55}$$

details on the procedures to integrate the MC and DP plasticity models are given in reference [36].
Furthermore, the energy dissipated during the formation of a shear band is related to the mode II fracture energy $G_f$, defined per unit area. This must be related to the plastic work $W_p$, defined per unit volume, dissipated during the plastic flow. Assuming that in the finite element discretization, strain localization occurs in a band of maximum resolution, one element thick, $h$:

$$W_p = \frac{G_f}{h} \quad (56)$$

The softening law for cohesion can be defined in different ways. In this work, exponential softening is considered:

$$c = c_0 \exp \left( -\frac{2H_s}{c_0} \frac{\varepsilon_p}{c_0} \right) \quad 0 < \varepsilon_p < \infty \quad (57)$$

With these softening law for cohesion, the plastic work done from the onset of plasticity ($t = 0$, $c = c_0$ and $\varepsilon_p = 0$) to full decohesion ($t = \infty$, $c = 0$ and $\varepsilon_p \neq 0$) is:

$$W_p = \int_{t=0}^{t=\infty} \dot{W}_p \, dt = \int_{t=0}^{t=\infty} \sigma : \dot{\varepsilon}_p \, dt = \frac{c_0^2}{2H_s} \quad (58)$$

Equating (56) and (58), the softening parameter $H_s$ depends on the material properties and the size of the finite element discretization:

$$H_s = \frac{c_0^2 h}{2G_f} \quad (59)$$

### 3.4 Orientation of the localization band

Strain localization in geomaterials reveals as shear bands, narrow bands of intense straining bounded by surfaces where strain (weak) discontinuities occur.

Several authors [37–45] have analytical and geometrical solutions for the orientation of discontinuity $S$ bands (see Fig. 3) in elasto-plastic materials using different strategies. All of them base their solutions on the so-called localization condition, as it is a necessary condition for the appearance of weak discontinuities and, subsequently, strain localization.

Differently, Cervera et al. [12,46,47] propose an alternative methodology to find analytical solutions for the band orientation. This procedure states the conditions for boundedness of stresses and full decohesion, which combined, are more stringent necessary conditions for the formation of the shear band. According to this, the band orientation in an associated plasticity model does not depend on the elastic constants (such as the Poisson’s ratio), but only on the plastic flow, determined by the yield criterion and the stress state. Table 1 shows analytical values of the localization angle of locale $\theta_{loc}$ for the MC and DP in plane stress.
and plane strain situations. Cervera et al. [18] have verified these results numerically for J2 plasticity and the DP model using an implicit mixed strain/displacement formulation.

4 Numerical examples

In this Section, the efficiency and robustness of the proposed explicit stabilized mixed strain–displacement formulation (MEX-FEM) are demonstrated by solving several benchmark tests. The different problems involve compressible and quasi-incompressible elasticity in dynamic and quasi-static conditions and perfect and softening plasticity with strain localization. They are also solved in 2D and 3D.

Simulations are performed with an enhanced version of the finite element program KRATOS [48,49], developed at the International Center for Numerical Methods in Engineering (CIMNE). Pre and post-processing is done with GiD, also developed at CIMNE [50]. The reference solutions for the 2D and 3D Cook’s membrane have been obtained with fine structured meshes of 4-noded quadrilaterals (40,166 nodes, 39,750 elements) and 8-noded hexahedra (142,191 nodes, 132,000 elements) with constant pressure and implicit HHT time integration.

4.1 Cook’s membrane. Compressible and quasi-incompressible elasticity

The proposed MEX-FEM formulation is first tested numerically on Cook’s membrane, with the geometry shown in Fig. 4. The problem is analyzed in 2D, under plane strain assumptions. Four finite element meshes are used, with progressive level of refinement, see Fig. 5. Both compressible and quasi-incompressible cases are considered with elastic properties: Young’s modulus $E = 200$ MPa and Poisson’s ratio $\nu = 0.30$ and $\nu = 0.499$. Material density is $\rho = 10$ kg/m$^3$.

Firstly, the transient dynamic analysis of the problem is addressed. In this case, the load $F$ at the free end of the short cantilever is applied instantly at $t = 0$, and it remains constant in time. For the integration in time, the time step is selected so that conditional stability is warranted [29]. The OSS method is used for the stabilization of the mixed problem, with algorithmic constants $c_u = 1.0, c_\varepsilon = 1.0$ and $L_0 = 50$ mm. In 2D, the size of the element is computed as $h = (4/\pi \cdot A)^{1/2}$, $A$ being the area of the element. The displacement subscale $\tilde{u}$ is computed using Eq. (44). Mass and stiffness proportional damping with $\alpha = 0.1$ and $\beta = 10^{-7}$ is used to filter out spurious high frequencies; this damping does not emerge in the low frequency response.

Figure 6 compares the evolution of the vertical displacement at point A (top right corner) and the mean stress at point B (bottom mid point), for the compressible case, Poisson’s ratio $\nu = 0.3$, using both the irreducible and the MEX-FEM formulation. As the mean-stress is continuous for the mixed $P1P1$ element, but discontinuous for the $P1$ irreducible element, a continuous field is obtained for the later

**Table 1** Analytical localization angles for MC and DP in plane stress and plane strain

| Model | Plane stress | Plane strain |
|-------|--------------|--------------|
| MC    | $\theta_{loc} = \left\{ \begin{array}{ll} 0^\circ & \text{if flow normal to plane } A - B \\ \pm \left( 45^\circ - \frac{\phi}{2} \right) & \text{if flow normal to plane } A - C \end{array} \right.$ | $\theta_{loc} = \pm \left( 45^\circ - \frac{\phi}{2} \right)$ |
| DP    | $\tan^2 \theta_{loc} = \frac{\sigma_1-2\sigma_2+2J_1/\eta}{2\eta-\sigma_2+2J_1/\eta}$ | $\tan^2 \theta_{loc} = \frac{\sigma_1-2\sigma_2+2J_1/\eta}{\sigma_1-\sigma_2+2J_1/\eta}$ |
for comparison, so that \( p_h = \mathcal{P}_h(p) \). Satisfactory results are obtained for the displacements in all cases (top row); the rate of convergence for the mean stress is noticeably lower in the irreducible case and very similar to that of the displacements for the mixed form.

Figure 7 shows corresponding results for the quasi-incompressible case, Poisson’s ratio \( \nu = 0.499 \). Here, the advantage of the proposed mixed formulation is evident. The irreducible formulation, on the one hand, grossly underestimates the vertical displacements, even for rather fine meshes; the phase error is also unacceptable. On the other hand, the mean stress field is highly unstable. Results obtained with the present mixed formulation are remarkably better, regarding amplitude and phase, both in the displacement and stress fields.

Next, the stationary problem is solved using a pseudo-transient analysis with over-damping to achieve a steady-state solution. The relative rate of convergence of the different formulations is shown in Figs. 8 and 9, for the compressible and quasi-incompressible cases, respectively. Results are also shown for the MEX-FEM formulation without displacement subscale, \( \tilde{u} = 0 \), as originally presented in reference [29].

For the \( \nu = 0.3 \) case, all the formulations converge satisfactorily to the correct values (1.84318 mm for the dis-

![Vertical displacement and mean stress plots](image)

Finally, Fig. 10 shows a contour fill of the mean stress field obtained on mesh $D$ for the case $\nu = 0.499$. Only the proposed MEX-FEM formulation is able to eliminate the pressure instability, showing the betterment provided by the displacement subscale in quasi-incompressible situations.

4.2 Cook’s membrane. Quasi-incompressible elasticity in 3D

In this Section, the Cook membrane problem in Fig. 5 is analyzed in 3D (thickness 10 mm) for quasi-incompressible elastic properties, Poisson’s ratio $\nu = 0.499$. Again, four finite element meshes are used, with progressive level of...

Fig. 11 Cook’s membrane. Meshes used for 3D analysis. $Nn$ number of nodes

refinement, see Fig. 11. In the tridimensional case, the size of the element is taken as $h = \left(\frac{6}{\pi \cdot V}\right)^{\frac{1}{3}}$, being $V$ the element volume. Time integration, numerical damping and stabilization parameters are selected as for the 2D case.

Results for the tridimensional dynamic analysis are shown in Fig. 12. Again, the irreducible $P1$ element shows an extremely poor performance due to volumetric locking. The computed displacements are underestimated, even in relatively fine meshes. Phase error is also severe. Mean stress is also unstable. Contrarily, the MEX-FEM formulation shows satisfactory results both in terms of displacements and mean stress.

Next, the problem is solved using a pseudo-transient analysis with over-damping to achieve a steady-state solu-
4.3 Prandtl’s punch test. Incompressible perfect plasticity

This 2D example in plane strain is often used to assess the computation of failure mechanisms and failure loads in plasticity models. Figure 15 shows the geometry and the mesh used in the present analysis. Because of symmetry, only half of the domain (the right half) is considered. Dimensions are: $L = 5$ m and $B = 1$ m. The MEX-FEM formulation with orthogonal subscale stabilization described in Sect. 2 is used,
Fig. 14 Cook’s membrane in 3D. Mean stress contours in Mesh D. $\nu$: 0.499

Fig. 15 Prandtl’s punch test. a Geometry, b FE mesh

with algorithmic constants $c_u = 1.0$, $c_c = 1.0$ and $L_0 = 5$ m employed for the stabilization parameters in Eq. (25). The domain is discretized with an unstructured mesh of 2438 nodes and 4731 linear elements, both for the irreducible ($P1$), and the MEX-FEM ($P1P1$) formulations. The problem is also analyzed with quadratic irreducible elements ($P2$). In all cases a constant velocity of $10^{-3}$ m/s is imposed in the indicated area. The quasi-static problem is solved using mass proportional damping, with $\alpha \Delta t = 0.1$.

Material properties are: density $\rho = 10^4$ Kg/m$^3$, Young’s modulus $E = 10^7$ KPa, Poisson’s ratio $\nu = 0.48$, initial cohesion $c_0 = 490$ KPa and friction angle $\phi = 20^\circ$. Both the perfectly plastic models of Mohr–Coulomb and Drucker–Prager are used; for the latter, parameters $\eta$ and $\varsigma$ chosen as indicated in Eq. (52). With these values, the analytical solution for the quasi-static problem is $P_{lim}/c_0 = 14.8$, where $P_{lim}$ is the total applied force to impose the velocity.

Figure 16 shows a contour fill of the equivalent plastic strain obtained with the MC model; the DP model produces very similar results. The collapse mechanism obtained using the proposed MEX-FEM formulation is very well defined. It coincides with the analytical solution and it is independent from the orientation of the mesh. Contrariwise, the solution obtained with the linear irreducible elements is strongly dependent on the mesh bias and it goes associated to severe stress-locking and mean stress oscillations. Using quadratic irreducible elements slightly improves the solution, but the stress oscillations are not fully eliminated.

Figure 17 shows the force–displacement curves for the different FE formulations and the two plasticity models considered. Note that MEX-FEM captures satisfactorily the peak load, with values of $P_{lim}/c_0 = 15.16$ for the MC model and $P_{lim}/c_0 = 15.22$ for the DP model, both in close agreement with the analytical value for the perfectly quasi-static problem. For the linear $FI – P1$ element, the volumetric locking is evident, and the peak load can not be identified. For the quadratic $FI – P2$ element, the limit load is $P_{lim}/c_0 = 15.56$, somewhat overestimated.
4.4 Perforated strip under tension. Strain localization in plane strain and stress

This 2D example consists in a simply perforated strip subjected to uniform tension, by applying uniform normal tractions at the free ends of the strip. The objectives of the benchmark are three-fold: (1) to determine numerically the localization angle $\theta_{loc}$ for varying friction angles $\phi$, for the MC and DP models, (2) to investigate the effect of the Poisson’s ratio in the localization angle and (3) to compare the results obtained numerically with the analytical solutions proposed in Table 1.

Dimensions are $l = 40$ m, $b = 20$ m and $d = 2$ m. Thickness is 1 m. Material properties are: Young’s modulus $E = 10$ MPa, Poisson’s ratio $\nu = \{0, 0.15, 0.30\}$, initial cohesion $c_0 = 10^9$ Pa, friction angle $\phi = \{0^\circ, 15^\circ, 30^\circ, 45^\circ, 60^\circ\}$.

Given the symmetry of the problem, only one quarter of the domain (top-right) is considered. The domain is discretized with 3758 nodes and 7274 elements. Figure 18 shows the geometry of the problem and the computational mesh. The MEX-FEM formulation with orthogonal subscale stabilization described in Sect. 2 is used, with algorithmic constants $c_u = 1.0$, $c_\varepsilon = 1.0$ and $L_0 = 10$ m employed for the stabilization parameters in Eq. (25). The problem is analyzed both in plane strain and plane stress conditions.

The plane strain case is considered first. The results from the analyses are presented in Table 2. The ability of the MEX-FEM formulation to capture the correct direction for the localization band, both for the MC and the DP models is remarkably demonstrated, in close agreement with the analytical predictions.

Figure 19 shows the calculated localization bands for different friction angles $\phi$, using the MC model, and represented as a contour fill of the equivalent plastic strain. The collapse mechanisms are completely independent of the mesh used, the same in all cases. For the DP model, similar results are obtained, see Table 2.

Table 3 compares the numerical results obtained in plane strain for two different values of Poisson’s ratio. It can be seen that the localization angle depends only on the plastic flow, as predicted analytically.

The plane stress case is now considered. Table 4 compares the localization angles obtained with the DP model in plane stress. Again, the agreement with the analytical predictions is remarkable, independently of mesh bias. Figure 20 shows some of the obtained fields of equivalent plastic strain. Note that for the DP model, the localization angle is substantially different in plane stress and plane strain.

The MC model in plane stress is now considered. For plane stress, the pure tension case in the MC model corresponds to one of the lines where two of the planes defining the yield criterion intersect, see Fig. 1. Therefore, two alternative solutions exist, with the plastic flow being normal to plane $A-C$ or $A-B$, respectively. In order to obtain one or the other solution, the applied state of stress is perturbed by lateral normal stress of 1 KPa, applied either in compression $t_x < 0$ or in tension $t_x > 0$. For $t_x > 0$, strain localizes in a horizontal band, independent from the friction angle, as it would occur for a Rankine model; however, for $t_x < 0$, local-

Strain localization in 3D

The last problem to be studied is a perforated thin cylinder subjected to two different actions: tension and torsion along its longitudinal axis. The dimensions of the cylinder are: length $h = 1.95$ m, external radius $r = 0.50$ m and thickness $t = 0.05$ m; the cylinder has a small square perforation in its midplane where stresses concentrate and one or more plastic strain localization helicoidal bands are initiated. For this geometry of the problem and for the actions considered,

Figure 22 shows the force–displacement curves obtained for the MC model in plane strain and the DP model in plane stress, respectively. Note that, in both cases, the peak load decreases as the friction angle increases.

4.5 Perforated thin cylinder under tension and torsion. Strain localization in 3D

The last problem to be studied is a perforated thin cylinder subjected to two different actions: tension and torsion along its longitudinal axis. The dimensions of the cylinder are: length $h = 1.95$ m, external radius $r = 0.50$ m and thickness $t = 0.05$ m; the cylinder has a small square perforation in its midplane where stresses concentrate and one or more plastic strain localization helicoidal bands are initiated. For this geometry of the problem and for the actions considered,
the stress state is plane; therefore, the localization angles are those in Table 1 [12,46,47]. Because of symmetry, only the top half of the cylinder needs to be discretized. Geometry and the structured FE mesh used, with 15,357 nodes and 59,880 tetrahedral MEX-FEM P1 P1 elements, are shown in Fig. 23.

The material properties are: density $\rho = 100$ Kg/m$^3$, Young’s modulus $E = 10^5$ KPa, Poisson’s ratio $\nu = 0.30$, initial cohesion $c_0 = 4$ KPa and fracture energy $G_f = 5$ N/m. Tension and torsion on the cylinder are induced by imposed displacements at the top plane at a velocity of $10^{-3}$ m/s.

Firstly, uniform longitudinal tension is studied. A von Mises plastic model is selected as yield criterion (Drucker–Prager with friction angle $\phi = 0^\circ$). Figure 24 shows three different views of the shear bands formed. The solution consists of two symmetrical helicoidal bands that start at the perforation and progress towards the free end of the cylinder $\pm 45^\circ$ with the horizontal plane, which is the direction of the minor principal stress [12,46,47]. The numerical solution coincides exactly with the analytical prediction.

Secondly, uniform longitudinal torsion is studied. In this case, the Mohr–Coulomb model is used with a friction angle $\phi = 45^\circ$. For this loading, the stress state in the walls of the cylinder is of pure shear, with principal stresses of the same value but opposite signs acting at $\pm 45^\circ$ with the horizontal plane. According to the analytical results in Table 1 [12,46,47], shear band must form at $\pm 22.5^\circ$ with the direction of minor principal stress, that is, at $22.5^\circ$ and $67.5^\circ$ with the horizontal plane. Both alternative solutions are shown in Figs. 25 and 26, respectively. In order to obtain one and the other, the torsional problem is slightly perturbed with a small longitudinal tension or compression, respectively.

Both for the cases of longitudinal tension and torsion, the analytical solutions are reproduced numerically with no spurious mesh bias. Therefore, the ability of the proposed formulation to address the problem of strain localization in

elasto-plastic 3D problems is assessed. It is noteworthy that no auxiliary tracking techniques are necessary.

5 Conclusions

This work proposes an explicit mixed strain–displacement finite element formulation (MEX-FEM), applicable to dynamic and quasi-static problems in computational solid mechanics involving quasi-incompressibility and strain localization. The formulation uses equal order interpolations and, in particular, linear/linear $P_1P_1$ elements are demonstrated (triangles in 2D and tetrahedra in 3D). The LBB inf-sup condition on the mixed problem is effectively circumvented using the variational multiscale method, selecting the strain and displacement subscales in the space orthogonal to the finite element interpolating spaces, respectively.

This provides a robust formulation which shows enhanced accuracy in the strain and stress fields when compared to the irreducible formulation and the ability to address quasi-incompressible problems when compared to previous versions on the mixed formulation that do not incorporate the displacement subscale. Additionally, an explicit implementation of the formulation, that does not require the solution of coupled full systems of equations, greatly simplifies its implementation and application.

The presented benchmark problems in 2D and 3D prove that the MEX-FEM formulation: (i) can be extended to the

quasi-incompressible elastic regime, (ii) can solve problems in the compressible and quasi-incompressible plastic regime, (iii) can satisfactorily solve quasi-static material physically problems involving strain localization, (iv) performs satisfactorily with directional inelastic behavior, without spurious stress locking and without the need of auxiliary discontinuity tracking procedures.
