Initiated by Phosphacyclohexadienyl Anions

The ability of phosphacyclohexadienyl anions \( [\text{Li}(1-\text{R}-\text{PC}_3\text{Ph}_2\text{H}_3)] \) \( [\text{R} = \text{Me} (1\text{a}), \text{nBu} (1\text{b}), \text{nBu} (1\text{c}), \text{Ph} (1\text{d}) \) and \( \text{CH}_3\text{SiMe}_3 (1\text{e})] \) to initiate hydrofunctionalisation reactions was investigated and compared with simple, commercially available compounds, such as \( \text{LiO} \)Bu, KOBu and nBuLi. All compounds are expedient catalysts for the hydroboronation of a wide scope of substrates, ranging from aldehydes to imines and esters. In the hydroboronation of carbon dioxide, however, only our system was observed to efficiently produce the desired methanol equivalents.

The past few decades have seen considerable strides in main group chemistry, both from a fundamental and applied point of view. One of the more attractive prospects is the utilisation of main group compounds as precious metal mimics, especially in terms of catalytic applications.\(^1\) The main goal is the eventual replacement of rare transition metal catalysts with an effective and more abundant main group counterpart.

The hydroelementation of unsaturated organic compounds, in particular hydroboronation and hydrosilylation, is a reaction that traditionally was firmly in the remit of precious metal catalysts.\(^2\) Hydrofunctionalisation processes are highly prevalent in industry; products from these reactions are used extensively in the production of fine chemicals, pharmaceuticals, lubricants, adhesives and insulation.\(^3\) The past decade has witnessed an influx of main group compounds capable of such transformations and in the case of hydroboration reactions, actually surpassing transition metal catalysts.\(^4\) Beside these rather sophisticated catalysts, recent years have also seen a plethora of reports with more easily accessible and commercially available compounds, which are able to effectively catalyse hydroelementation reactions. Alkoxides,\(^5\)\(^6\) potassium fluoride/carbonate,\(^7\) Grignard reagents,\(^8\)\(^9\)\(^10\) as well as \( \text{n-butyl} \) lithium\(^11\)\(^12\) all were able to hydroborate ketones to their respective alkoxyborane. Furthermore, \( \text{Leung} \) and co-workers reported the catalyst-free reduction of ketones with pinacolborane in solvent-free conditions at elevated temperatures.\(^11\)

Compared to hydroboronation, hydrosilylation reactions catalysed by main group compounds are much less common. Noteworthy examples include the highly Lewis acidic borane \( \text{B(C}_3\text{F}_4)_3 \) \(^12\) and phosphenium cations\(^13\) as well as commercially available bases, such as \( \text{KOBu} \)\(^14\)\(^15\), KOH\(^15\) and \( \text{Cs}_2\text{CO}_3 \)\(^15\). Although promising, main group systems still do not match the efficiency and scope of many transition metal catalysts in terms of the hydrosilylation of carbonyl compounds, thus the demand for more effective main group catalysts remains high.

Our efforts to devise new main group element based catalysts involved investigating phosphacyclohexadienyl anions \( 1\text{a-e} \) (Figure 1), which are readily synthesised by treatment of 2,4,6-triphenylphosphinine with alkyl lithium reagents.\(^16\) These species (typically referred to as \( \lambda^3 \)-phosphinine anions) are best described as anionic tertiary phosphines, although they display various properties, including nucleophilicity, which makes them suitable for hydrofunctionalisation processes. In particular, the phosphacyclohexadienyl anions \( 1\text{a-e} \) exhibit a unique combination of reactivity and selectivity in hydrofunctionalisation reactions, opening new avenues for the development of main group-based catalysts.

**Figure 1.** Catalytic hydrofunctionalisation of carbonyl compounds using phosphacyclohexadienyl salts \( 1\text{a-e} \) (\( \text{R} = \text{Me} (1\text{a}), \text{nBu} (1\text{b}), \text{nBu} (1\text{c}), \text{Ph} (1\text{d}), \text{CH}_3\text{SiMe}_3 (1\text{e}) \)). TOF = turnover frequency, the TOF refers to an average value for a complete reaction.
distinct chemical properties. We envisioned that the highly reactive nature of these anions would lend themselves to small molecule activation/catalysis. Here we show that such anions have excellent properties for the hydrofunctionalisation of ketones, imines and esters. We also compared our findings with commercially available catalysts such as nBuLi, LiOtfBu and KOrBu.

To test the catalytic potential of anions 1a–e, we performed a series of hydroboration/silylation reactions. Acetophenone hydrofunctionalisation was chosen as the benchmark reaction to probe the capability of 1a–e, and to compare their catalytic activity (Table 1). While all compounds displayed high efficiency, the tBu derivative, 1c performed the best (see Table 1, entry 3) and thus was chosen for further optimisation in both hydroboration and hydrosilylation reactions. Using 1c at a loading of 0.01 mol%, acetophenone was fully converted to 1-phenylethan-1-ol in less than 8 minutes at T = 23 °C. This equates to a TOF of ≥ 75 000 h⁻¹, which is among the most rapid of any reductions employing pinacolborane to date.

The catalyst was able to readily hydroborate a wide array of substrates, including aldehydes, ketones, esters, alid- and ketimines as well as benzoic acid (see Table S1 and S2, SI for details). Besides its good functional group tolerance, 1c also showed exceptional chemoselectivity in the presence of other reducible moieties such as nitro, nitrile, pyridyl, and alkenyl groups. In the hydrosilylation reactions, 1c showed a similar substrate scope, excluding only esters, benzoic acid and ketimines (see SI).

It is known that simple inorganic bases such as alkali metal tert-butoxides and n-butyllithium can also catalyse the hydroboration of acetophenone, but with comparatively higher catalyst loadings and longer reaction times. Considering these results, we were interested in how well our catalytic system compares to such commercially available catalysts. With previously reported results in mind, we anticipated to see 1c to be faster than these compounds. Surprisingly, initial tests using 2-methylacetophenone gave similar activity for all catalysts (see SI). In order to better compare the catalytic activities, ReactIR measurements were conducted (Table 2), revealing high activities that surpassed expectations for these commercial compounds, especially for n-butyl lithium. Benzophenone was used as a sterically more demanding substrate to give a more manageable reaction timeframe. Both alkoxydes achieved a conversion of at least 50% within 105 seconds, while 1c and n-butyl lithium only required 60 and 30 seconds, respectively. These short reaction times translate into an approximate turnover frequency (TOF) of 64 800 h⁻¹, 35 000 h⁻¹, 34 300 h⁻¹ and 153 500 h⁻¹ for 1c, LiOtfBu, KOrBu and nBuLi, respectively. To our knowledge, the best known main group based catalyst for hydroboration reactions is Okuda’s lithium triphenylborohydride complex containing tris[2-(dimethylamino)ethyl]amine, which was reported to achieve a TOF of at least 66 666 h⁻¹. This TOF, however, was calculated after the reaction was completed, meaning the actual TOF could be much higher. Taken altogether, it is clear that nBuLi possesses great catalytic activity, rivaling even the most active main group hydroboration catalysts.

A similar trend was also observed for the hydroboration of octan-2-one, N-benzylidenaniline and ethyl acetate with pinacolborane (Table 3). Low catalyst loadings are sufficient to achieve high conversions in the course of 5–30 min. While in most cases KOrBu was observed to be slightly slower, especially in the hydroboration of the ethyl acetate, there was no major difference between 1c, nBuLi and LiOtfBu. As potassium tert-butoxide has been reported as an efficient hydroboration catalyst, we proceeded to also test 1c, LiOtfBu, and n-butyl lithium in the hydrosilylation of acetophenone. In these reactions, however, none of the lithium salts was able to compete with potassium tert-butoxide hinting at a more pronounced cation effect on the activity in hydroboration reactions (see Table 4).

As all tested catalysts displayed the ability to reduce very demanding substrates, we proceeded to test their ability to catalyse the hydroboration of CO₂ (Table 5). With LiOtfBu and KOrBu, no conversion was observed even at elevated temperatures. 1c and nBuLi both were able to fully consume pinacolborane, as observed in the ¹H and ¹B NMR spectra.

(a) [H] NMR spectrum has a major signal (δ = 24.3 ppm) that can be assigned to the borolane (4) and [N(4)][1-tBu-Ph₃B₃H₆] (Scheme 1). Although we can isolate the presumed adduct (2), we were unable as of yet to crystallographically characterise it. Upon testing 2 in the hydroboration of 2'-methylacetophenone, only a slight decrease in catalytic activity was observed when compared to 1c (Table S5, SI). When stoichiometric amounts of HBpin were added to 2, the desired product (5) as well as the released catalyst 1c could be observed as the main products. Altogether, these experiments suggest the mechanism starts with the formation of an adduct between the ketone and 1c, which then reacts with the reducing agent. The catalytic cycle is subsequently closed by the release of 5 and the reformation of 1c.

Studies of 2'-methylacetophenone hydroboration in THF and benzene using [K(1-tBu-PC₅H₃)]₃ (3) and [N(nBu)]₃[1-tBu-PC₅H₃] (4) revealed similar catalytic activities as observed for 1c (Table S5, SI). This was also observed for the alkoxides MOMe and MOtBu (M = Li, Na, K). Therefore, it can be inferred that the cation only has a minor influence on the reactivity. Similar conversions of 73–89 % were observed for all alkoxides with the exception of NaOMe, which gave a conversion of only 30 % (see SI).

In order to shed light onto the mechanism, further ReactIR kinetic measurements were conducted. The reaction order was determined using the method of initial rates and the time normalisation approach (see SI for details).²² The results clearly suggest a zero-order dependence on ketone concentration and a first order dependence on 1c and HBpin. Furthermore, a stoichiometric reaction between 1c, ketone and HBpin was performed. The full consumption of HBpin was observed and upon comparing the integrals of the methyl signals of the ketone (δ = 22.2 ppm) with the signals of the product (δ = 23.0 ppm) the yield of the desired borolane can be estimated to be >95 %. The ¹B{¹H} NMR spectrum shows a major signal (δ = 22.2 ppm that can be assigned to the borolane (5) with two minor signals (<10 %) at δ = 6.3 and 5.8 ppm that could not be identified. The ³P{¹H} NMR shows 1c to be the main component (86%) with the formation of a new signal at δ = −24.3 ppm (11%). The signal at δ = −24.3 ppm was also observed, when reacting 1c with the ketone in the absence of borane. Therefore, we propose this to be an adduct of the ketone with 1c (Scheme 1). Although we can isolate the presumed adduct (2), we were unable as of yet to crystallographically characterise it. Upon testing 2 in the hydroboration of 2'-methylacetophenone, only a slight decrease in catalytic activity was observed when compared to 1c (Table S5, SI). When stoichiometric amounts of HBpin were added to 2, the desired product (5) as well as the released catalyst 1c could be observed as the main products. Altogether, these experiments suggest the mechanism starts with the formation of an adduct between the ketone and 1c, which then reacts with the reducing agent. The catalytic cycle is subsequently closed by the release of 5 and the reformation of 1c.

Studies of 2'-methylacetophenone hydroboration in THF and benzene using [K(1-tBu-PC₅H₃)]₃ (3) and [N(nBu)]₃[1-tBu-PC₅H₃] (4) revealed similar catalytic activities as observed for 1c (Table S5, SI). This was also observed for the alkoxides MOMe and MOtBu (M = Li, Na, K). Therefore, it can be inferred that the cation only has a minor influence on the reactivity. Similar conversions of 73–89 % were observed for all alkoxides with the exception of NaOMe, which gave a conversion of only 30 % (see SI).

In order to shed light onto the mechanism, further ReactIR kinetic measurements were conducted. The reaction order was determined using the method of initial rates and the time normalisation approach (see SI for details).²² The results clearly suggest a zero-order dependence on ketone concentration and a first order dependence on 1c and HBpin. Furthermore, a stoichiometric reaction between 1c, ketone and HBpin was performed. The full consumption of HBpin was observed and upon comparing the integrals of the methyl signals of the ketone (δ = 22.2 ppm) with the signals of the product (δ = 23.0 ppm) the yield of the desired borolane can be estimated to be >95 %. The ¹B{¹H} NMR spectrum shows a major signal (δ = 22.2 ppm that can be assigned to the borolane (5) with two minor signals (<10 %) at δ = 6.3 and 5.8 ppm that could not be identified. The catalytic cycle is subsequently closed by the release of 5 and the reformation of 1c.

When comparing the effectiveness of phosphacyclohexadienyl anions in hydroboration and hydrosilylation catalysis of...
polar substrates with those for commercially available bases LiO还不如Bu, KOBu and nBuLi, we have found that these catalysts also show a remarkable efficiency, rivalling the most active catalysts available to date. All of these catalysts can reduce very challenging substrates, such as imines and esters. However, LiO还不如Bu, KOBu and nBuLi were ineffective in the hydrogenation of COposites. This is in contrast to compounds 1a–e which were able to efficiently reduce CO$_2$ to the corresponding methanol equivalent under ambient conditions with HBpin and HBCat.

On-going work in our group concerns the utilisation of this methodology and the development of asymmetric hydro-functionalisation reactions.
