Abstract
The paper presents the design and the implementation of a direct predictive control of a variable speed wind energy conversion system. The conversion chain uses a Doubly Fed Induction Generator DFIG whereas the control method is based on a Finite States Model Predictive Control FS-MPC. The proposed control method selects the optimal switching state of the two levels back to back power converter that minimizes the cost function, where this optimal voltage vector is applied on the output of the power converter in next sampling time. The proposed predictive control strategy uses only one sample time prediction and it is intuitive since it is very simple for implementation. In order to adjust the measured rotor currents to track their references, the error between orthogonal rotor current components predictions to their computed values used to select the optimal vector and applied on the power converter in rotor side CSR in next sampling time. On other side, based on the error between the active and reactive power prediction and their references of the electrical grid, the predictive algorithm control of the grid side converter CSG kept the Dc-link voltage constant and guarantee that the whole system functioning with unity power factor. The experimental results confirm the advantages of using this structure for wind energy conversion system and the effectiveness of the proposed control strategy.

variable speed wind energy conversion system, DFIG, finite set model predictive control, cost function

1 Introduction
The global consumption of electricity observed over the last few decades is strongly linked to the development of industry, transport and communications. Fossil fuels, such as petroleum, coal and natural gas, are the most widely used fuels for the production of electric power today because of low production costs but lead to a massive release of gas pollutants. Thus, electricity production from fossil fuels is responsible for 40\% of global CO\textsubscript{2} emissions. On the other hand, their rate of regeneration is extremely slow on a human scale. This will lead, in the short term, to a non-zero risk of depletion of these resources. In this context, most developed countries have focused on clean, non-polluting renewable sources of energy. Among the various technologies developed, the turbine occupies a considerable place. In 2021, the 93 GW of new installations brings total cumulative installations up to 743 GW in the world [1].

Electric power conversion systems using a Doubly Fed Induction Generator (DFIG) are the most popular configurations due to its advantages in the medium and high power such as: a variable speed operating range and operating capacity in the four quadrants [2, 3]. In general, the stator winding of DFIG is directly connected to the grid providing electric power with constant voltage and frequency, while the rotor winding is connected to the grid via a tow levels back-to-back converter (two cascaded converters connected with a direct current DC link). The Rotor Side Converter RSC controls the direct and quadrature rotor currents components of the generator while the Grid Side Converter GSC controls the DC link voltage and ensures operation of large power factor. As the rotor speed is fluctuating, the electric power of the rotor is reversible depending on whether the machine operates in either sub synchronous mode or super synchronous mode. Other advantages of DFIG machines can be cited, such as the adaptability of the power factor, better efficiency and the ability to control the reactive power without

capacitive support. Also, they allow a significant reduction of the power converters size and cost since the size of the converters is related to the speed variation range, typically around +/-30% of the synchronous speed. Note that the main advantage of the WECS based DFIG machine is the perfect decoupling between active and reactive power control by controlling rotor currents [4].

Among the two last decades, several control strategies for WECSs based DFIG have been reported in specialist literature starting from the basic idea that control does significantly improve all aspects of WECS and the most widely used techniques may be classified within the Field Oriented Control (FOC) techniques [5, 6], the Direct Torque Control (DTC) [7–9], and Direct Self Control (DSC) [10].

Recently; Finite-States Model Predictive Control (FS-MPC) appears as a complete and accurate approach to control power converters due to its fast dynamic response, no need for linear controllers in inner loops, no need for modulator (as in PWM or SVM modulation), completely different approach compared to PWM and SVM modulations, extremely simple, good performance and can be implemented with standard commercial microprocessors [11]. The method uses the model of the system to predict for one step ahead prediction the behavior of the variables for each switching state. For the selection of the appropriate switching state to be applied to the system a quality function must be defined. The cost function is then evaluated for the predicted values on each sampling interval and the optimal switching state that minimizes the quality function is selected to apply during the next sampling interval [12, 13].

In this paper, we will extend the application and implementation of FS-MPC to WECS based on DFIG since the most papers in this field are mostly related to classic control methods. The superiority of FS-MPC over conventional control will be confirmed by simulation and experiment results.

2 System modeling

Several variable-speed WECS configurations are being widely used in [14]. The schematic diagram of a DFIG based wind energy generation system studied in this paper is shown in Fig. 1 where the rotor winding is connected to the utility grid via two power converters. The Rotor Side Converter RSC controls the direct and quadrature components of the rotor currents while the Grid Side Converter GSC controls the DC link voltage and ensures operation of large power factor [15].

![Fig. 1 Schematic diagram of a DFIG based wind energy generation system](image)

2.1 DFIG modeling

The equations that describe a doubly fed induction generator in a \(dq\) reference frame where different parameters of the machine appear in a continue form are identical to those of a squirrel cage induction generator; the only exception is that the rotor winding is not short-circuited. We assume balanced voltages and non-ground connection points. Two orthogonal axes are defined, the \(d\) and \(q\) axis. The rotor voltages are given by Eq. (1) [16]:

\[
\begin{align*}
V_{dr} &= R_{dr} i_{dr} + \frac{d\psi_d}{dt} - w_s \omega_p \psi_q, \\
V_{qr} &= R_{qr} i_{qr} + \frac{d\psi_q}{dt} + w_s \omega_p \psi_d.
\end{align*}
\] (1)

In order to obtain a decoupled control of stator active-reactive powers, the DFIG model requires all quantities to be expressed under stator flux orientation concept and assuming that the stator resistance is small when compared to the stator reactance for medium and high power size machine, the stator flux can be computed as [17, 18]:

\[
\begin{align*}
\psi_{ds} &= \psi_s, \\
\psi_{qs} &= 0 \rightarrow \psi_s = \frac{V_s}{\omega_s}.
\end{align*}
\] (2)

Then the torque is simplified into:

\[C_{em} = p \psi_{ds} i_{qs} = -p \frac{M}{L_s} \psi_{ds} i_{qr},\] (3)

The stator active-reactive powers expressions are:

\[
\begin{align*}
P_s &= V_{ds} i_{ds} + V_{qs} i_{qs} = -V_s \frac{M}{L_s} i_{qr}, \\
Q_s &= V_{dr} i_{dr} = \frac{V_s^2}{w_s L_s} - \frac{V_s M}{L_s} i_{qr}.
\end{align*}
\] (4)

The dynamics of the rotor current components can be expressed then from relations (Eqs. (2), (3) and (4)) by:
\[
\begin{align*}
V_{dc} &= R_i \frac{di}{dt} + \sigma L_i \frac{di}{dt} - sw L_i i_q, \\
V_{dq} &= R_i i_q + \sigma L_i \frac{di}{dt} + sw L_i i_d, \\
V_{dq} &= R_i i_d + \sigma L_i \frac{di}{dt} - sw L_i i_q \frac{MV_s}{L_s}.
\end{align*}
\]

\(2.2\) Modeling of the grid network and DC-link voltage

In order to decouple and further simplify the grid-side converter system linked to the electrical network through an RL filter, the synchronous angular speed is typically chosen equal to the angular speed of the network voltage, and the axis \(d\) of the rotating frame is aligned with the grid voltage vector:

\[
V_{dg} = v_g; V_{eq} = 0,
\]

the \(dq\) current components of the electrical network voltages are given by:

\[
\frac{di}{dt} = \frac{1}{L_e} (v_{dp} - R_i i_{dq} + \sigma L_i i_{eq} - v_{dq}),
\]

\[
\frac{di}{dt} = \frac{1}{L_e} (v_{eq} - R_i i_{eq} - \omega L_i i_{eq} - v_{dq}),
\]

where \(v_{dp}\) and \(v_{eq}\) denote the output voltage components of the converter; \(v_{dq}\) and \(v_{eq}\) represent the grid voltage components; and \(i_{dq}\) and \(i_{eq}\) are the phase current components in \(dq\) reference frame.

The orientation of the grid voltage not only simplifies the filter current equations, but also reduces the calculations of active and reactive grid power. Here, instantaneous active and reactive power inputs are given by:

\[
\begin{align*}
P_g &= v_i i_{dq}, \\
Q_g &= -v_i i_{eq}.
\end{align*}
\]

The two power converters of the wind power conversion system (GSC and RSC) are interconnected via a DC bus so allows power transfer between the rotor of the DFIG and the electrical grid [19], the DC-link capacitor voltage can be expressed in terms of the DC-link capacitor current as follows:

\[
V_{dc} = \frac{1}{C} \int i_c dt,
\]

where the \(dc\) current \(i_c\) in super synchronous mode given by the transfer of the electrical power from the electrical grid to the rotor:

\[
i_c = I_{GSC} - I_{RSC}.
\]

The \(C\) is the DC-link capacitor, \(I_{GSC}\) is the output current of the RSC and \(I_{RSC}\) is the output current of the GSC.

\(2.3\) Two level voltage source inverter model

To describe the inverter output voltages, the concept of complex space vector is applied. For a two-levels voltage source inverter feeding a symmetrical three-phase grid connected system given in Fig. 2, each leg is composed of two by-directional switches \((S_i, S_j, i = a, b, c)\) where \(a, b, c\) three phases. The switching states \(S\) determined by gating signals are given in vector form as follows [20]:

\[
S = \frac{2}{3} (S_a + aS_b + a^2 S_c),
\]

where \(a = e^{j \frac{2\pi}{3}}\). \(S_i\) takes the value of 0 if \(S_i\) is off and \(S_i\) is on, \(S_j\) takes the value of 1 if \(S_j\) is on and \(S_j\) is off.

The output voltage space vectors of the inverter are:

\[
V = \frac{2}{3} (v_{AN} + av_{BN} + a^2 v_{CN}),
\]

\((v_{AN}, v_{BN}, v_{CN})\) are the phase to neutral \((N)\) voltages.

As it is well known, there are eight possible voltage vectors that the inverter can apply to the grid terminals. By using these switching functions the grid space voltage vector can be expressed as:

\[
V (S_a, S_b, S_c) = \frac{2}{3} V_{dc} \left( S_a + S_b e^{j \frac{2\pi}{3}} + S_c e^{j \frac{4\pi}{3}} \right),
\]

where \(V_{dc}\) is the De-link voltage.

According to the combinations of switching modes, the space vectors \(V_7(0,0,0)\) and \(V_8(1,1,1)\) are the space zero

![Fig. 2 Tow level Neutral Point Clamped inverter topology (2L-NPC)](image-url)
voltage vectors and the others are the space nonzero active voltage vectors as shown in Fig. 3.

Also, the inverter output voltage is related to DC link voltage by:

\[ V = V_{dc} S. \]  

(15)

The inverter output voltage vector is kept constant during the switching period, so the inverter current and, hence, the grid currents can be controlled by choosing the appropriate voltage vector.

3 Predictive Control of the back to back converter

3.1 Control of the rotor side converter

3.1.1 Predictive model of the rotor current

For a two-level voltage source inverter or rectifier, the finite set of states of the switches \( S_1, \ldots, S_6 \) contains only six different voltage active vectors and two null voltage vectors [21], the dynamics of the rotor current components can be expressed from relations Eq. (5) by:

\[
\begin{align*}
\frac{di_{dr}}{dt} &= \frac{1}{\sigma L_r} \left( V_{dr} - r_i i_{dr} + s \omega L_r i_{qr} \right) \\
\frac{di_{qr}}{dt} &= \frac{1}{\sigma L_r} \left( V_{qr} - r_i i_{qr} - s \omega L_r i_{dr} - s \frac{MV_s}{L_s} \right),
\end{align*}
\]  

(16)

where \( V_{dr, qr} \) are the output voltage space vectors generated by the inverter.

By approximating the derivative \( \frac{di_{dr, qr}}{dt} \) in Eq. (16) for a sampling time \( T \) by:

\[
\frac{di_{dr, qr}}{dt}\bigg|_{k} = \frac{1}{T} \left( i_{dr, qr}(k + 1) - i_{dr, qr}(k) \right).
\]  

(17)

Prediction of rotor current components can be made for one step ahead prediction as:

\[
\begin{align*}
&i_{dr}(k+1) = \frac{T}{\sigma L_r} \left( V_{dr}(k) - r_i i_{dr}(k) + s \omega L_r i_{qr}(k) \right) + i_{dr}(k) \\
&i_{qr}(k+1) = \frac{T}{\sigma L_r} \left( V_{qr}(k) - r_i i_{qr}(k) - s \omega L_r i_{dr}(k) - s \frac{MV_s}{L_s} \right) + i_{qr}(k).
\end{align*}
\]  

(18)

3.1.2 Minimization of a cost function

The cost function \( C \) summarizes the desired behavior of the inverter. The control objective is to get high performance in term of rapid and precise dynamic current control response by using a quadratic cost function that minimizes the error between reference currents to their computed values. The predictions on rotor currents are used to evaluate the impact of every voltage vector on the WECS. The cost function is formulated as [22–24]:

\[
C_{RSC}(j) = \left[ \left| i_{dr}^* - i_{dr}(j+1) \right|^2 + \left| i_{qr}^* - i_{qr}(j+1) \right|^2 \right].
\]  

(19)

The flow chart of the proposed predictive control is given by Fig. 4, where for each rotor voltage vector the cost function \( C \) is evaluated and the voltage vector that minimizes the cost function is then applied during the next sampling period according to the receding horizon control [22].

![Fig. 4 Flow chart of the predictive algorithm for the RSC](image-url)
3.2 Control of the grid side converter

3.2.1 Predictive model of the grid power

By applying the Euler approximation method described above to Eq. (7), we obtain the following discrete model:

\[
\begin{align*}
    i_{dg}(k+1) &= \frac{T_s}{L_g}(v_{dp}(k) - R_g i_{dg}(k) + \omega_g L_g i_{qs}(k)) - v_{dg}(k) + i_{dg}(k), \\
    i_{qs}(k+1) &= \frac{T_s}{L_g}(v_{qp}(k) - R_g i_{qs}(k) - \omega_g L_g i_{dg}(k)) + i_{qs}(k), \\
    \begin{cases}
        P_g(k+1) = v_g(k) i_{dg}(k+1) \\
        Q_g(k+1) = -v_g(k) i_{qs}(k+1)
    \end{cases}
\end{align*}
\]

3.2.2 Minimization of cost function

The objective of the grid side converter GSC control is to regulate the DC bus voltage and controlling the active and reactive power passing through it. The power factor can be set to one simply by imposing a reactive power reference equal to zero. In order to assure this objective, the error between the active/reactive power references and the active/reactive power predicted components is chosen to represent the cost function and given by [25]:

\[
    C_{GSC}[\tau] = |P_g^\tau - P_g[\tau+1]| + |Q_g^\tau - Q_g[\tau+1]|.
\]

4 Control strategy

Several control algorithms of the WECS have been reported recently through the literature [4, 26–28], whether for a wind system feeding an isolated load, or the network. The configuration of the present work is given by Fig. 5 and Fig. 6, where the rotor of the DFIG is connected to the grid via a back to back power converter and a RL filter assuming that +/- 30% of the DFIG nominal power is exchanged with the grid whereas the rest of this power is directly generated by the stator to the grid. The Maximum Power Point Tracker MPPT controller is used to track closely the maximum power point of the wind turbine (turbine rotor works closely on the Optimal Regime Characteristic ORC [29, 30]. In this work don't studying the MPPT controller.

The global control structure of the studied WECS using back to back based on two level source voltage converters is given by Figs. 5 and 6. Fig. 5 illustrates the principal work of the model predictive control to control the active and reactive powers of the rotor of DFIG fed by the 2L-NPC inverter. Fig. 6 shows how the grid side converter GSC controls the DC-link voltage and ensures the unity power factor. Technique control is based on model predictive control.

4.1 Control of DFIG

Generally, the field oriented control (FOC) concept of the DFIG is based on stator active-reactive power control, however this solution is suitable only when the machine operates in normal regime, but when the grid is affected by
disturbances and faults which is not considered in this study, the measure of stator powers is not appropriate, so the rotor currents are chosen to be directly controlled [4, 26–28].

The rotor currents references can be expressed by:

\[ i_{qr}^* = -\frac{L_s}{pM\psi_s}C_{em}, \]  
\[ i_{dr}^* = \frac{\psi_s}{M} - \frac{L_s}{M\psi_s}Q_s^*. \]  

The stator reactive power \( Q_s^\ast \) is set to 0, then the new value of the reference direct rotor current given as follows:

\[ i_{dr}^\ast = \frac{\psi_s}{M} = \frac{V_s}{M\psi_s}. \]  

The reference for the stator active power \( P_s^\ast \) is then given as:

\[ P_s^\ast = \frac{a_0}{p}C_{em}. \]  

4.2 Control of the power flow side the electrical grid

The main goal of the grid side converter control is to keep the dc-link voltage constant and to achieve a desired reactive power reference. In normal operation, the power flowing through the grid and rotor side converters is balanced, that is, \( P_r \) is equal to \( P_{c}^\ast \) so the DC-link voltage is constant [31]. A PI regulator used to control the dynamic response of the DC link voltage, the output of the PI regulator is multiplying by a DC link voltage to obtain the DC link power \( P_{c,ref} \). The DC bus voltage regulation loop is shown in Fig. 7.

\[ P_{c,ref} = i_{c,ref}V_{dc}. \]  

The power appearing in the rotor circuit corresponds to the output power of the DC-link voltage added to the output power of the network (hyperf synchronous operation):

\[ P_r = P_g + P_{dc,ref}. \]  

The active power reference transiting the grid side converter \( P_{g,ref} \) is obtained by subtracting the power \( P_{c,ref} \) of the active power appearing in the rotor of the DFIG \( P_r \) (hyper-synchronous operation) [32]:

\[ P_{g,ref} = P_r - P_{dc,ref}. \]  

5 Experimental implementation and validation

5.1 Experimental setup

The experimental validation of the power wind conversion system was performed on an experimental test rig at reduced power (DFIG and DC-motor with 3KW), which is shown in Fig. 8 with the parameters as indicated in Table 1 in the Appendix.
The predictive control algorithm has been implemented using a two host PCs running with MATLAB-Simulink 2012a software through Real-Time Interface (RTI). The back-to-back converter between the rotor of the DFIG and the electrical grid contains a two Semikron power converters (inverter or rectifier corresponding the power flow) separate by capacitance bank with 2200 \( \mu F \). Each of them controlled separately by two TI TMS320F240 DSPs cards from Texas Instrument. An interface board is used between the dSPACE card and IGBT gate drivers for adapting the interface output signals of the dSPACE TTL (0/5V) with the logic levels of the input signals of the SKHI 22 driver (0/15 V). Measuring the position of the rotor of the DFIG is performed using an encoder incremental placed on the shaft of the generator. The grid voltage, the Dc-link voltage, the continue current of the DC-motor, the stator currents and the rotor currents are measured with LEM transducers. The inductance of 32 \( mH \) is inserted between the rotor of the DFIG and the RSG for smoothing the rotor currents. To feed the DFIG we used the transformer with one input of 220 V and two outputs with 220 V for stator and 127 V for rotor. In order to fix the speed of the DC-Motor at desired value we used the chopper four quadrants, where the rotor of the DFIG coupled directly to a DC machine. The schematic diagram is shown in Fig. 9.
5.2 Simulation results
The proposed predictive control of the studied WECS given by Fig. 5 is tested in Matlab/simulink environment with a sampling time of 90 μs, considering a DFIG of 3 KW for reduced generation system whose parameters are given in the Appendix. One-step prediction horizon is considered in all the simulation tests. The results are presented in order to show the performance, the speed time response, and the accurate of the tracking reference. The simulations divide in two-parts GSC and RSC simulation.

5.2.1 GSC results
Fig. 10 shows the DC link voltage. As it can be seen, after a short transient time (<0.2 s), is regulated at its reference value (220 V). The ripple of this DC voltage is less than 2 V. At 1.25 s the Fig. 10 presents test, which was response to the step change of DC-link voltage reference value from 220 V to 250V, where the DC link voltage response needs just 0.055 s to achieve a new reference (250 V).

The grid reactive power tracks to its reference with fast dynamics. The decoupled control for active and reactive powers (thus for d and q-axis currents, respectively) has been achieved as demonstrated in Fig. 11 and Fig. 12.

Fig. 13 shows the electrical network current, which is in phase with the electrical network voltage. And this compatibility we obtained from the effectiveness of the control technique and forcing it to follow the desired reference.

5.2.2 RSC results
In this section, we find the results of the rotor side converter controlling the DFIG. In order to shows the performance of the control algorithm we made several tests (varying in \(d\) or \(q\) reference current component or the speed generator like hypo synchronous mode to hyper synchronous mode).
Fig. 11 Active and reactive powers

Fig. 12 dq controlled filter components

Fig. 13 Grid current and grid voltage
As illustrates Figs. 14 to 16 the measured $d$ or $q$ currents are tracked their references precisely and in decoupled form that’s mean we can control $d$ or $q$ separately.

5.3 Experimental results and discussion

5.3.1 GSC results

Figs. 17 to 19 show the dynamic response of the DC-link voltage. We can see with clarity the capacitor voltage kept their reference in mode permanent without static error. The dynamic response of the Dc-link voltage takes 20 ms to reach their reference. That result slow response of PI controller. But this controller allows the bidirectional power flow between the rotor of DFIG and electrical grid. In other side, when the DC-link voltage reference value change from 220 V to 250 V the active power and line current are increase. The grid voltage and grid current are in phase, that’s mean the power factor is unity and obtained when the reactive power set to zero. It is verified that the current is practically sinusoidal. The great ripple in measured active and reactive power caused by a limited choice of the sampling time in experimental setup with dSPACE 1104 card ($T_s = 90 \mu s$).

5.3.2 RSC results

Figs. 20 and 21 illustrates an experiment based on the change in the value of the current $i_{dr^*}$, where we started by a positive value 4 A in the time domain [0–9 s], and then we reduced it to a negative value -2A in the time domain [1–2.6 s] and finally we returned it to a positive value 4.5 A in the period [2.6–3.6 s]. On the contrary, the value of the $i_{qr^*}$...
Fig. 16: $i_{dr}$ varied and $i_{qr}$ fixe

Fig. 17: DC-link voltage

Fig. 18: Active and reactive power
Fig. 19 Grid current and grid voltage

Fig. 20 $i_d$ varied and $i_q$ fixed

Fig. 21 Rotor currents and generator speed
current remained constant 0 A during this test. Here we clearly notice that the change in the value of the \( i_{dr}^{*} \) current is followed by a change in the speed of the motor proportional to the change in the current where if the value of the current increases, the speed also increases and vice versa. Here, the DFIG functioning in mode hypo-synchronous (the speed of machine is less than to the synchronous speed 1500 tr/min).

Figs. 22 and 23 presents the same tests in the previous figure but here we changed the value of the current \( i_{qr}^{*} \), where we started by -4A in [0–1.6 s], 1 A in the [1.6–2.75 s] and finally -4A in the period [2.75–3.6 s]. The \( i_{dr}^{*} \) is take the fixe value in all test +4A. Also, the change in the value of the current \( i_{qr}^{*} \) directly affects the value of the speed. Contrary to the first test the DFIG functioning in mode hyper-synchronous (the speed of machine is greater than to the synchronous speed 1500tr/min).

The Fig. 24 shows how the direction of the three-phase rotor current changes with the change in the value of the speed and this result when we change the value of the current \( i_{qr}^{*} \) from 2.5 A to -2.5 A. PCC performance is examined when varying the rotor speed from 1440 to 1640tr/min, as shown in Fig. 24. During the test, the rotor \( d \)-axis current is constant at 5 A but the \( q \)-axis current is varied from 2 A to -2.5 A. As seen, during the speed variation, the rotor and stator currents are well controlled. The rotor current frequency decreases initially due to the reduced rotor slip, reaching zero at the 1500-r/min synchronous speed, and increases after passing 1500 r/min.

As we see in Figs. 20, 22 and 24 the tracking performance shows high dynamic performance for both \( d-q \) axis rotor current since the \( d-q \) axis are perfectly decoupled and track their references accurately and precisely.

![Fig. 22 \( i_{dr} \) fixe and \( i_{qr} \) varied](image)

![Fig. 23 Rotor currents and generator speed](image)
Figs. 21, 23 and 25 shows the rotor current and speed mechanics during a transition from hypo-synchronous regime to hyper-synchronous speed. These results confirm that the DFIG can operate in both regimes while allowing a smooth transition during the change of regime.

Fig. 26 shows the rotor current $i_{dr}$, the stator current $i_{as}$ and the stator voltage $v_{as}$. It is seen that the stator current and voltage are not in phase and not in opposite in phase because the value of $i_{dr} \neq \frac{v}{w_M}$. Furthermore, the rotor current operates with a low frequency along the wind speed.
profile and its amplitude is depending on the amplitude of the wind speed (where the value of the $i_{r}$ or $i_{s}$ increases or decreases the amplitude of the rotor current also increases or decreases, respectively). It should also be noted that the frequency of the rotor current is much lower compared to that of the stator current. Also, when the stator current is in phase opposition with the voltage, thus allowing the generator to deliver only active power to the network.

6 Conclusions
A direct predictive control strategy is proposed and applied to control a wind energy conversion chain based on a doubly fed induction generator using a two level back-to-back converter. The most advantage of the proposed control method is its simplicity in implementation, since the method avoids the use of linear or nonlinear controllers except for the external wind speed loop and there is no need for any type of modulator, such as in PWM modulation, which can reduce the overall cost of the drive system. The control scheme is very simple and uses discrete model of the converter to predict the behavior of rotor currents and to obtain the best suited converter switching state. Simulation results show accurate tracking performance with a significant reduction of oscillation of current that improves the efficiency of the conversion chain. The proposed controller algorithm is designed and implemented on experimental bench of a 3 kW-DFIG in a real time via a dSPACE 1104 card. The obtained results validate the control strategies, and provided a good dynamic performance in term the response time, robustness and dynamics accurate tracking.

Acknowledgments
The authors wish to thank the financial support from the university of L’Arbi Ben M’hidi of Oum El bouaghi Algeria. Also, I would like to express my sincere gratitude to my co supervisor Prof. Abdellatif Reama, professor at the Ecole d’ESIEE of Paris for the continuous support of my internship study and research, for his patience, motivation, enthusiasm, and immense knowledge. His guidance helped me in all the time of research. This experimental work is realized just in 90 days (the duration external internship in Ecole d’ESIEE Paris).

### Table 1 Wind turbine system parameters

| Variables | Description | Experimental value |
|-----------|-------------|--------------------|
| $V_s$     | RMS supply grid voltage phase (V) | 220                |
| $f_s$     | Supply Frequency (Hz) | 50                 |
| DFIG      |             |                    |
| $V_r$     | RMS supply stator voltage phase (V) | 220                |
| $V_r'$    | RMS supply rotor voltage phase (V) | 110                |
| $P_n$     | Nominal power (KW) | 3                  |
| $R_r$     | Rotor Resistance (Ω) | 1.7329             |
| $R_s$     | Stator Resistance (mΩ) | 88                 |
| $M$       | Mutual Inductance (mH) | 168.6              |
| $L_s$     | Stator Inductance (mH) | 175.2              |
| $L_r$     | Rotor Inductance (mH) | 175.2              |
| $P$       | Number of pair of the pole | 2                  |
| DC-banc   |             |                    |
| $C$       | DC-link capacitance (uf) | 2200               |
| $V_d$     | DC-link voltage (V) | 250                |
| Grid      |             |                    |
| $L_g$     | Grid inductor (mH) | 32                 |
| $R_g$     | Grid resistor (Ω) | 2.8                |
