To investigate coordinated RNA synthesis and degradation, we developed comparative dynamic transcriptome analysis (cDTA). cDTA provides absolute rates of mRNA synthesis and decay in Saccharomyces cerevisiae (Sc) cells with the use of Schizosaccharomyces pombe (Sp) as an internal standard. cDTA uses nonperturbing metabolic labeling that supersedes conventional methods for mRNA turnover analysis. cDTA reveals that Sc and Sp transcripts that encode orthologous proteins have similar synthesis rates, whereas decay rates are fivefold lower in Sp, resulting in similar mRNA concentrations despite the larger Sp cell volume. cDTA of Sc mutants reveals that a eukaryote can buffer mRNA levels. Impairing transcription with a point mutation in RNA polymerase (Pol) II causes decreased mRNA synthesis rates as expected, but also decreased decay rates. Impairing mRNA degradation by deleting deadenylase subunits of the Ccr4–Not complex causes decreased decay rates as expected, but also decreased synthesis rates. Extended kinetic modeling reveals mutual feedback between mRNA synthesis and degradation that may be achieved by a factor that inhibits synthesis and enhances degradation.

[Supplemental material is available for this article.]

Cellular gene expression is controlled by mRNA levels, which are governed by the rates of nuclear mRNA synthesis and cytoplasmic mRNA degradation. The rates of mRNA turnover are regulated during RNA polymerase (Pol) II transcription in the nucleus (Fuda et al. 2009), whereas bulk mRNA degradation occurs in the cytoplasm (Eulalio et al. 2007; Parker and Sheth 2007; Wiederhold and Passmore 2010). During transcription, the mRNA receives a 5′-cap and a 3′-poly(A) tail. The mature mRNA is then exported to the cytoplasm, translated, and eventually degraded cotranslationally (Hu et al. 2009). Cytoplasmic mRNA degradation generally begins with shortening of the poly(A) tail by the Ccr4–Not complex, which contains the deadenylases Ccr4 and Pop2 (also known as Caf1) (Liu et al. 1998; Tucker et al. 2001). The mRNA is then decapped and degraded by exonucleases from both ends. Despite the spatial separation of mRNA synthesis and translation/degradation, there is evidence that these processes are coordinated (Lotan et al. 2003; Lotan et al. 2007; Harel-Sharvit et al. 2010).

To investigate coordinated RNA synthesis and degradation, absolute changes in synthesis and decay rates must be measured after introducing a genetic perturbation that impairs either synthesis or degradation. Rates of mRNA synthesis and degradation can be measured by dynamic transcriptome analysis (DTA) in yeast (Miller et al. 2011). Newly synthesized RNA is labeled with 4-thiouridine (4sU), which is taken up by cells that express a nucleoside transporter. After 6 min of labeling, total RNA is extracted and separated into newly synthesized (labeled) and pre-existing (unlabeled) fractions. Total, labeled, and unlabeled fractions are analyzed with microarrays and the data are fitted with a dynamic kinetic model to extract synthesis and decay rates. Whereas DTA accurately measures the relative rates for different RNAs within a single sample, it cannot compare rates from different samples, since the samples differ by an unknown global factor (Miller et al. 2011). In standard transcriptomics, comparison between samples with different mRNA levels may be achieved by counting cells and spiking RNA standards into the samples (Holstege et al. 1998; Wang et al. 2002; van de Peppel et al. 2003). However, such normalization does not take into account differences in cell lysis and RNA extraction efficiency, which can vary so strongly that no conclusions are possible.

To enable normalization between DTA measurements of different samples, we extended DTA to comparative DTA (cDTA). In cDTA, a defined number of labeled fission yeast Schizosaccharomyces pombe (Sp) cells is added to the budding yeast Saccharomyces cerevisiae (Sc) sample before cell lysis and RNA preparation, and is used as an internal standard. Thereby, cDTA allows the absolute quantification and accurate comparison of mRNA synthesis and decay rates between samples. cDTA is a novel method that monitors absolute changes in eukaryotic mRNA metabolism upon genetic perturbation. We applied cDTA to Sc cells that are impaired in either mRNA synthesis or degradation. This revealed compensatory changes in degradation and synthesis, respectively, which indicates that a eukaryote can buffer mRNA levels to render gene expression robust. After our work was completed, an independent study appeared that postulates a similar compensation on an evolutionary scale (Dori-Bachash et al. 2011).

Results

Comparative dynamic transcriptome analysis (cDTA)

To measure changes in mRNA synthesis and decay rates between different strains of budding yeast (Sc), we included the distantly related fission yeast (Sp) in our DTA protocol as an internal standard (Fig. 1). We counted Sc sample cells and Sp control cells and...
mixed them in a defined ratio (Methods). The resulting cell mixture was lysed, total mRNA extracted, labeled RNA purified, and microarrays were hybridized as described (Miller et al. 2011). The RNA mixture was quantified on a microarray that contains probes for both Sc and Sp transcripts (Affymetrix GeneChip Yeast Genome 2.0 Array) (Miller et al. 2011). We used 4-thiouracil (4tU) instead of 4sU for Sc RNA labeling, because it is taken up by Sc (Munchel et al. 2011) without expression of a nucleoside transporter (Miller et al. 2011). 4tU labeling did not affect normal cell physiology (Supplemental Fig. S1) and allowed growth of yeast in YPD instead of selective medium. We quantified only labeled and total RNA, because the unlabeled fraction was not required for rate extraction. We refer to this protocol as comparative DTA (cDTA).

We first tested whether the Sc sample showed cross-hybridization to Sp array probes and vice versa. When either a Sc or Sp sample was hybridized to the array, cross-hybridization occurred for a minor fraction of the probes (Methods) when a conservative intensity cut-off of 4.5 (log intensity values after preprocessing) was used (Fig. 2A). Cross-hybridizing probes were excluded from further analysis, leading to loss of only 16 out of 10,799 probe sets (Methods). The mixing ratio of Sc:Sp samples was tuned to 3:1 to maximize the overlap of the Sc and Sp expression intensity distributions (Fig. 2B). This ensures that after calibration most Sc and Sp probe intensities are in the linear measurement range of the microarray, an important prerequisite for our calculations. We restricted our analysis to RNAs with log intensity signals above 4.5 and below 8 (Fig. 2B).

Rate extraction from cDTA data

To obtain absolute synthesis and decay rates for Sc and Sp, we derived the ratios of labeled to total RNA intensities Cc and Csp for Sc and Sp, respectively. These ratios set the global median level of synthesis and decay rates and rely on a robust previous estimate of the median Sp half-life (Miller et al. 2011) for which labeled, total, and unlabeled RNA fractions were available. Once Csp is known, the measured levels of the Sp standard can be used to calibrate the Sc data (Fig. 3A). This new normalization method allows rate estimation from labeled and total quantities alone (Methods). Our published median half-life for Sc mRNAs (Miller et al. 2011) enabled determination of the median Sp half-life relative to Sc (Supplemental Fig. S2). We measured growth curves and obtained a doubling time of 90 min for Sc in YPD medium at 30°C and 116 min for Sp in YES medium at 32°C (Supplemental Fig. S3). These doubling times were used in kinetic modeling (Miller et al. 2011). We confirmed that the rates obtained by cDTA are essentially the same as the ones previously obtained by DTA (Table 1; Supplemental Fig. S2). RNA half-lives that were recently determined by 4tU pulse-chase labeling in Sc are 1.5-fold longer (Munchel et al. 2011), likely because a very long labeling time was used that allowed for thionucleotide reincorporation after mRNA decay. We calculated mRNA synthesis rates as the number of complete transcripts made per cell and per 90 min (the cell cycle time for wild-type Sc), using a new estimate of 60,000 transcripts per yeast cell (Zenklusen et al. 2008) instead of the previously used, older, and fourfold lower estimate (Hereford and Roshbash 1977). For Sp, we estimated the number of transcripts from the observed 2.51-fold cumulative total RNA level to be 150,801. Our rate estimates are unaffected by the efficiency of 4tU labeling, which varies between strains and experiments (Supplemental Fig. S1).

For normalization between different Sc samples, we linearly rescaled all array intensities such that the total and labeled Sp fractions have a median intensity of 1 or csp (Fig. 3B). We assessed the accuracy of the cDTA procedure by estimating the intensity ratios of Sc:Sp cells that were mixed at 1:1, 3:1, and 10:1. The correct values were recovered with an accuracy of 5% (Fig. 2D). Selected mRNA levels of the 1:1 and 10:1 ratio mixtures were additionally quantified by RT–qPCR (Methods). The expected ratio of the four tested Sc transcripts was recovered within a relative error of 9% when normalized to two housekeeping Sp genes (data not shown).

In summary, cDTA normalization removes the major sources of experimental deviations between samples in RNA-labeling efficiency, cell lysis, RNA extraction, RNA biotinylation and labeled RNA purification, and array hybridization. cDTA detects global changes between Sc samples, in contrast to standard normalization procedures that eliminate global changes, because they assume constant median RNA levels.

cDTA supersedes conventional methods

Conventional methods measure mRNA half-lives by inducing transcription arrest and following changes in mRNA levels over time. Transcription arrest has been achieved by adding the transcription inhibitor 1,10-phenanthroline (Dori-Bachash et al. 2011) or by shifting the temperature-sensitive mutant strain rpb1-1, which carries point mutations in the largest subunit of Pol II (Nonet et al. 1987), to the restrictive temperature (Holstege et al. 1998; Wang et al. 2002; Grigull et al. 2004; Shalem et al. 2008). To investigate whether the latter method yields reliable data or whether it perturbs mRNA metabolism, we regenerated the rpb1-1 strain and analyzed it with cDTA using published growth parameters (Holstege et al. 1998) (Methods). This revealed that mRNA synthesis rates were decreased globally by a factor of 2.7 already at the permissive temperature of 30°C (Fig. 4A). After 24 min at the restrictive temperature, mRNA synthesis rates had decreased further by a factor of 3.4, but recovered essentially to the rates measured at the permissive temperature after 66 min (Fig. 4A).

These observations indicated that the mRNA metabolism in the rpb1-1 strain is already perturbed at the permissive temperature, and that the temporary changes in mRNA metabolism ob-

Figure 2. Establishing the cDTA protocol. (A) Assessment of cross-hybridization. Scatterplot of log intensities of 10,928 Affymetrix probe sets. The values on the x- resp. y-axis are obtained as the mean of two pure Sc resp. Sp replicate samples that were hybridized to the arrays. Sc and Sp probe sets (heat colored and gray scaled, respectively) can be separated almost perfectly. A total of 23 out of 5771 Sc probe sets show intensities above a (log) background intensity threshold of 4.5 in the Sp sample, whereas eight out of 5028 Sp probe sets were above background in the Sc sample. These 31 probe sets are regarded as affected by cross-hybridization (green circles). Of these, 16 probe sets were excluded from analysis because all probes were affected by cross-hybridization (Methods). (B) Linear measurement range. Exemplary illustration showing that the relation of mRNA concentration (real amount) and mRNA intensity (fluorescent scanner readout) follows the Langmuir adsorption model (Hekstra et al. 2003; Held et al. 2003, 2006; Skvortsov et al. 2007). The green line indicates linearity. (Black line) Sigmoidal behavior, resulting from noise at low-hybridization levels and saturation effects at high-hybridization levels. (Gray stripe) Linear measurement range that we defined as an intensity range of 4.5–8 (natural log basis) based on noise signals below 4.5, for example, for probes that detect transcripts of genes that were knocked out and based on observed saturation effects above 8. (C) Calibration of Sc:Sp cell mixture ratio. The optimal cell mixture ratio has been chosen to maximize the number of probes for both Sc and Sp that fall into the linear measurement range (B). Sc and Sp cells were mixed in Sc:Sp ratios of 1:1, 3:1, and 10:1. The respective median mRNA level ratios are 0.3, 0.95, and 3.02. Log (RNA intensity) distributions of Sc (red) and Sp (gray) are shown. The median intensity level of Sp is approximately three times higher than that of Sc. As a consequence, a Sc:Sp cell mixture ratio of 3:1 was used. (D) Comparison of the three different cell mixtures of (C) in pairwise log–log scatter plots. All arrays are normalized to a common median of 4052 probe sets (gray-scaled). A total of 4475 Sc probe sets (those in the linear measurement range) are shown in heat colors. The parallel offset of the RNA intensity distributions of Sc from the main diagonal measures the mRNA level differences of Sc and Sp. The corresponding measured offsets are 3.14, 9.46, and 3.01 (Supplemental Fig. S4).  

Comparison of mRNA metabolism in distant yeast species

As an immediate result, cDTA reveals similarities and differences in the mRNA metabolism of Sc and Sp. First, the median mRNA synthesis rates are very similar in Sc and Sp (Fig. 5A). The median synthesis rate was 53 mRNA per cell and 90 min for wild-type Sc, and 44 mRNA per cell and 90 min for Sp. Second, Sp mRNAs have about fivefold longer half-lives on average than Sc mRNAs, with a median of 59 min (Fig. 5A; Supplemental Fig. S4), compared with 12 min for Sc. As expected, the cDTA-derived Sp half-lives show a good correlation with half-lives obtained by another nonperturbing metabolic labeling (Amorim et al. 2010). Furthermore, reprocessing the data of Amorim et al. (2010) with our cDTA algorithm, which takes into account the labeling bias and an additional parameter to correct for cell growth, increases the correlation to our results and leads to a median half-life of 50 min, in good agreement with an estimate of 59 min in our study (Supplemental Fig. 5B). Third, the overall mRNA levels in Sp were about 3.1-fold higher than in Sc. Since the haploid Sc cells with a median volume of 42 μm³ are approximately two- to threefold smaller than Sp cells with a median cell volume of ~115 μm³ (Jorgensen et al. 2002; Neumann and Nurse 2007), the higher mRNA levels apparently lead to similar cellular mRNA concentrations. The change in mRNA levels is mainly a global multiplicative change (R² = 0.82, Supplemental Fig. S4). 

Serious at the restrictive temperature are mainly due to a heat-shock response. To test this, we conducted a corresponding heat-shock experiment on wild-type cells. We analyzed the total mRNA from this experiment together with the data from the rpb1-1 mutant by conventional decay time series analysis (Holstege et al. 1998; Wang et al. 2002; Grigull et al. 2004; Shalem et al. 2008). The obtained mRNA half-lives during heat shock correlated very well with data derived from the rpb1-1 mutant strain and with published half-lives obtained with this strain (Fig. 4B). The obtained half-lives were shorter than the half-lives measured in unperturbed cells, likely because mRNA degradation was down-regulated during the stress response. There was also a good correlation with half-lives obtained after adding 1,10-phenanthroline and even with our previous data obtained during the osmotic stress response (Miller et al. 2011), if processed in the conventional way. This indicates that all of these data are dominated by perturbations in mRNA metabolism that result from a general stress response. In contrast, published half-lives derived from metabolic RNA labeling (Munchel et al. 2011) and our cDTA-derived half-lives do not correlate with data obtained by perturbing conventional methods. We conclude that conventional methods for estimating mRNA half-lives using the rpb1-1 mutant strain or transcription inhibition cannot be used to obtain reliable half-life estimations.
In highly conserved proteins show similar levels, but a faster turnover protein genes (Fig. 5A). More generally, transcripts that encode drop-off rate in Sp synthesis and decay rates (Fig. 5B; Supplemental Fig. S4). This analysis revealed concentrations, there is a minor fraction of transcripts that behave globally shifted decay rates, to reach similar cellular mRNA concentrations at similar mRNA synthesis rates, despite their larger volume.

We investigated whether mRNA sequence conservation correlates with a conservation of total RNA levels, synthesis rates, or decay rates (Fig. 5B; Supplemental Fig. S5). This revealed a conservation of the relative total levels of mRNAs that encode orthologous proteins in Sc and Sp. The levels of mRNAs that encode proteins with an amino acid sequence identity of at least 25% (2568 mRNAs) show a high Spearman correlation of 0.69. Synthesis rates correlate well between both species (Spearman correlation 0.61), but the half-lives show only a fair correlation (Spearman correlation 0.4). Although the data suggest that Sc cells have globally shifted decay rates, to reach similar cellular mRNA concentrations, there is a minor fraction of transcripts that behave exceptionally. In particular, 93 Sp transcripts show almost unaltered mRNA levels (<1.5-fold), but significantly higher synthesis and decay rates (>1.5-fold), and are enriched for ribosomal protein genes (Fig. 5A). More generally, transcripts that encode highly conserved proteins show similar levels, but a faster turnover in Sp (Fig. 5B). We also assessed the correlation of synthesis rates with transcript lengths, and revealed a substantially higher Pol II drop-off rate in Sp (Supplemental Fig. S5).

Impaired mRNA synthesis is compensated by decreased degradation

We applied cDTA to the question of whether the speed of Pol II is relevant for setting the cellular rates of mRNA synthesis. We used a yeast strain that carries the non-disruptive point mutation N488D in the largest Pol II subunit Rpo21 (also known as Rpbl) (rpb1-N488D). This mutation slows down Pol II speed in RNA elongation assays in vitro (Malagon et al. 2006) and is located near the active site (Cramer et al. 2001). We subjected this strain and an isogenic wild-type strain to cDTA, and collected two biological replicates that showed a Spearman correlation of 0.99 for total and labeled RNA levels. This normalization allows for a direct comparison of Sc data between experiments. Shown are both replicates for each of the four cDTA experiments.

| Table 1. Median mRNA half-lives and synthesis rates of Sc and Sp transcripts |
|------------------|-----|-----|
| Species          | cDTA | DTA |
|------------------|-----|-----|
| Median mRNA half-life (min) | Sc 12 | 11.5 |
| Sp 59 | N.A. |
| Median mRNA synthesis rate (mRNAs per cell and cell cycle time)* | Sc 33 | 18 (72)* |
| Sp 44 | N.A. |

The cDTA contains the estimates obtained from using the labeled:total ratio of the complementary strain and the known total and labeled Sc:Sp ratios to calculate the missing labeled:total ratio, i.e., LSp/TSp = (LSp/TSc)(TSP/TSc)(LSc/LSp). The DTA column shows the Sc half-life estimate obtained from Miller et al. (2011). Note that the Sc estimates are virtually identical to ours, although we used a different labeling technique (4U) instead of 4sU and had spiked-in Sp controls in the sample.

*Please note that we previously used in our calculations a total number of transcripts per cell of 15,000 according to our estimate (Zenklusen et al. 2008), whereas we now used a recent estimate of 60,000 (Zenklusen et al. 2008). If the same number of transcripts is used, the median synthesis rate obtained by DTA would be 72, comparable to our new estimate obtained by cDTA, despite the difference in media and cell cycle time (Miller et al. 2011).
Impaired degradation is compensated by decreased synthesis

The observed synthesis-decay compensation implies that cells buffer total mRNA levels. If true, cells should also be able to compensate for a mutation that impairs mRNA degradation with a change in mRNA synthesis rates. To investigate this, we applied cDTA to mutant yeast strains with global defects in mRNA degradation. The choice of mutant was difficult, since RNA degradation involves multiple enzymes in the nucleus and cytoplasm (Houseley and Tollervey 2009). We decided to use mutant strains that lack either one of the two catalytic subunits of the Ccr4–Not complex, Ccr4 or Pop2, which show a defect in mRNA deadenylation, a rate-limiting step in mRNA degradation (Tucker et al. 2002). As predicted, mRNA decay rates were globally decreased in the Δccr4 and Δpop2 strains, and changed on average by a factor of 0.43 and 0.16, respectively (Fig. 6C). This suggests that Ccr4 and Pop2 mRNA degradation factors are used globally.

In both degradation-deficient knock-out strains, an unexpected decrease in mRNA synthesis rates was observed (Fig. 6C). Synthesis rates were changed by a factor of 0.49 and 0.38 in the Δccr4 and Δpop2 strains, respectively, limiting the increase in total mRNA levels due to highly defective degradation to a factor of only 1.18 and 1.75, respectively (Fig. 6C). This effect could be observed directly in the labeled fractions of the Δccr4 and Δpop2 strains. Only 62% or 46% of the RNA was labeled within the same labeling time, indicating lower synthesis rates. Thus, the defects in RNA degradation in these strains are at least partially compensated by decreased mRNA synthesis rates in order to buffer mRNA levels. This mutual compensation cannot be explained by measurement variance. A variation analysis for the estimation of the median synthesis-decay compensation implies that cells buffer total mRNA levels. If true, cells should also be able to compensate for a mutation that impairs mRNA degradation with a change in mRNA synthesis rates. To investigate this, we applied cDTA to mutant yeast strains with global defects in mRNA degradation. The choice of mutant was difficult, since RNA degradation involves multiple enzymes in the nucleus and cytoplasm (Houseley and Tollervey 2009). We decided to use mutant strains that lack either one of the two catalytic subunits of the Ccr4–Not complex, Ccr4 or Pop2, which show a defect in mRNA deadenylation, a rate-limiting step in mRNA degradation (Tucker et al. 2002). As predicted, mRNA decay rates were globally decreased in the Δccr4 and Δpop2 strains, and changed on average by a factor of 0.43 and 0.16, respectively (Fig. 6C). This suggests that Ccr4 and Pop2 mRNA degradation factors are used globally.

Figure 4. Comparison of cDTA with conventional methods. (A) Box plots of the expression distributions of the total and the labeled (newly synthesized) mRNA after cDTA normalization, obtained from the wild-type and the rpb1-1 mutant before, and 24 and 66 min after the shift to restrictive temperature. Transcriptional activity is roughly restored in both strains after 66 min. The global shifts in labeled expression are only slightly more pronounced in the rpb1-1 mutant, indicating a dominant role of heat shock in the profiles of rpb1-1. (B) Correlation analysis of mRNA half-life measurements. The heatmap shows pairwise Spearman correlation coefficients of half-life measurements (white: negative or zero correlation; purple: perfect correlation). The published half-life estimates except for Munchel et al. (2011) were obtained by experiments using transcriptional arrest. The estimates of Holstege et al. (1998), Wang et al. (2002), Grigull et al. (2004), and Shalem et al. (2008) were obtained using a yeast strain containing the Pol II temperature sensitive mutant rpb1-1. Dori-Bachash et al. (2011) used the transcription inhibitor 1,10-phenanthroline.
whose activity is a function of their mRNA concentrations $s$. The offset of gray lines to parallel black lines indicates $Sp:Sc$ ratios of median decay rates, synthesis rates, or total mRNA (0.20/0.83/2.72). Dashed gray lines indicate 1.5-fold changes from the median (gray lines). Color scheme corresponds to folds in total mRNA (magenta, positive log fold; green, negative log fold). A set of genes that show higher decay and synthesis rates (1.5-fold and adjusted P-value 0.5%), but almost unchanged (<1.5-fold) total mRNA (93 transcripts, striped area) was selected and tested with a Bayesian network-based gene-set analysis (MGSA) (Bauer et al. 2010). In this gene set, the ribosomal protein genes were enriched (blue dots; ellipse shows the 75% region of highest density). (A) A rigid derivation and an extensive discussion of the model's assumptions are given (Methods; Supplemental Method S8). Here, we compare synthesis and decay rates of a gene between two conditions $C$ and $C'$:

$$\frac{dg}{dt} = SR(g, s) - DR(g, d) = \mu_s f(s) - g \lambda_f h(d).$$

The left-hand sides of Equations (2) and (3) can be evaluated by cDTA. The left-hand side of Equation (2) is substantially smaller than 1 for virtually all measurements $g', g$, and for both de-adenylation mutants (Fig. 6B). For these mutants, we also know that $\mu_s = \mu'_s$, and consequently $f(s') > f(s)$. We also observe that $g' > g$ and $s' > s$, from which we conclude that $f$ is monotonically decreasing. This implies that $S$ acts as a transcription inhibitor. In the slow Pol II mutant, we observe $\lambda_f = \lambda'_f$. Using a similar argument as above, Equation (3), and cDTA data of the slow Pol II mutant, we conclude that $h$ is monotonically increasing, implying that $D$ is a degradation enhancer. These conclusions could only be derived because cDTA enables the comparison of global synthesis and decay rates. The results would be identical if $S$ and $D$ were the same molecule. Thus, the most simple explanation of our observations is the existence of a factor that serves as an inhibitor of transcription and an enhancer of degradation and shuttles between the nucleus and cytoplasm.

**Discussion**

A systemic investigation of gene expression requires quantitative monitoring of cellular mRNA metabolism. In particular, a technique is required to quantify absolute mRNA synthesis and decay rates on a genome scale upon genetic perturbation. Here, we provide such a technique, which we refer to as comparative dynamic transcrpthonome analysis (cDTA). cDTA is based on nonperturbing metabolic RNA labeling in mutant and wild-type budding-yeast cells and the use of fission yeast cells as an internal standard. cDTA is a nonperturbing method for monitoring mRNA turnover and supersedes conventional methods, which require transcription inhibition, resulting in a stress response and perturbation of mRNA metabolism.

cDTA improves our previous DTA protocol (Miller et al. 2011) in several respects. First, cDTA provides reliable estimates of the absolute synthesis and decay rates, thereby allowing for a direct comparison of rates between different yeast strains. Second, cDTA uses 4U instead of 4sU for RNA labeling, allowing for standard media and abolishing the need for a nucleoside transporter. Third, cDTA requires only two instead of three microarray measurements per rate estimation. As an immediate result, cDTA revealed that $Sp$ and $Sc$ cells have similar synthesis rates, but $Sp$ RNAs have about fivefold longer mRNA half-lives, leading to similar cellular mRNA concentrations despite a different cell volume.

Application of cDTA to $Sc$ cells expressing a Pol II point mutant that elongates mRNA slowly in vitro showed that mRNA elongation is a critical determinant for mRNA synthesis in growing cells in vivo. It also revealed that cells compensate for low synthesis rates by lowering decay rates, thus stabilizing mRNAs and buffering their levels. Application of cDTA to two mutant strains that lack
either one of the two catalytic subunits of the mRNA deadenylase complex Ccr4-Not showed not only the expected defect in mRNA degradation, but also a compensatory decrease in mRNA synthesis, also leading to a buffering of mRNA levels. This indicated the existence of a feedback loop that connects mRNA synthesis and degradation and serves to buffer mRNA levels. These results support published evidence for a global control of mRNA levels in dependence of cell size (Zhurinsky et al. 2010). This global control of mRNA levels occurs despite the separation of mRNA synthesis and degradation into nuclear and cytoplasmic compartments.

The mechanisms underlying the synthesis-decay feedback loop and the buffering of mRNA levels are unclear. The feedback loop may be a result of a physical and functional coupling between the various parts of mRNA metabolism. Transcription is coupled to mRNA processing and export (Maniatis and Reed 2002), and translation is coupled to mRNA degradation (Coller and Parker

Figure 6. cDTA reveals changes in mRNA metabolism upon genetic perturbation. (A) Linear scatter plots (heat-colored) of mRNA synthesis rates, decay rates, and total mRNA levels in wild-type and mutant rpb1-N488D yeast strains as measured by cDTA. Slopes indicate global shift ratios of median synthesis rates, decay rates, and total mRNA of the rpb1-N488D mutant strain compared with wild type (0.26/0.31/0.75). (B) Alternative representation of the data from A in a single scatter plot comparing the changes in mRNA synthesis rates (log folds, x-axis) and decay rates (log folds, y-axis) in the rpb1-N488D mutant strain compared with the wild-type strain. Each point corresponds to one mRNA. The density of points is encoded by their brightness (grayscale). Contour lines define regions of equal density. The center of the distribution is located at (−1.8, −1.6), indicating that there is a global shift in the median synthesis rate by a factor of 0.26 (shift of the horizontal red line relative to the dashed x-axis line), and a global shift in the median decay rate by a factor of 0.31 (shift of the vertical red line relative to the dashed y-axis line). The global change in total mRNA levels is predicted by the offset of the diagonal red line from the dashed main diagonal, which corresponds to a change by a factor of 0.75. The number in brackets following this number (0.75) is the global change as it has been observed in the total mRNA measurements, which agrees well with the predicted number. The changes in total RNA levels do not exactly equal the quotient of synthesis and decay rate changes, due to an additional parameter for cell growth. (C) Scatter plots as in B comparing synthesis rates, decay rates, and total mRNA levels of Δccr4 and Δpop2 mutant strains to wild-type yeast. Ratios of median synthesis rates, decay rates, and total mRNA of the Δccr4/Δpop2 mutant strain compared with wild type are 0.49/0.39, 0.43/0.16, and 1.15/1.74, respectively. (D) Coupling of synthesis and decay rates, on the absolute level. For each condition, the median synthesis rate (y-axis) and degradation rate (x-axis) is shown (dark dots). (Dashed lines) Fold induction/repression relative to wild type. The dots lie approximately on a line with positive slope, indicating synthesis-decay compensation. A variation analysis for the estimation of the median synthesis and decay rates with cDTA has been performed. The ellipses show the 95% bootstrap confidence regions in each condition. The main axes of the ellipses reveal that the errors in the estimation of synthesis and decay rates are not independent, yet small enough to prove that the coupling is not due to estimation variance.
before flash-freezing in liquid nitrogen. Sp cells were grown in YES medium overnight, diluted to OD_{500}=0.1, and grown to OD_{500}=0.8. 4SU was solved in ddH_{2}O (50 mM) and added to a final concentration of 500 μM, and cells were labeled for 6 min. Cells were harvested by centrifugation at 2465g for 3 min. Other steps were as above. A 4-liter-culture of Sp cells was labeled to generate a stock and eliminate errors by variations in the standard. Cells were counted as above. Sp cells were mixed with Sc cells in a 1:3 ratio, resulting in 4 × 10^8 cells in total. Total RNA extraction, labeled RNA purification, as well as sample hybridization and microarray scanning were as previously described (Miller et al. 2011). For the cDTA analysis of rpb1-1 strains, overnight cultures were diluted in fresh medium to an OD_{500} of 0.15 (125 mL cultures, 160 rpm shaking incubator, 30°C). At an OD_{500} of 0.9 (time point:18 min), RNA was labeled. Eighteen minutes later (time point 0 min) cultures were shifted to 37°C by adding the same volume of 42°C-tempered medium. RNA was again labeled 18 min and 60 min after heat shock (time points +24 min and +66 min, respectively).

**Methods**

**Yeast strains and growth curves**

Strains RPB1 and rpb1-N488D (GYR 3020 and GYR 3027, respectively) were generously provided by Mikhail Kashlev (Malagon et al. 2006). Genotypes of GYR 3020 and GYR 3027 are MATα, his3Δ1, leu2Δ0, lys2Δ0, met15Δ0, trp1Δ::hisG, URA3::CMV-tTA RPO21, and MATα, his3Δ1, leu2Δ0, lys2Δ0, met15Δ0, trp1Δ::hisG, URA3::CMV-tTA rpb1Δ-N488D. For cDTA we used Sc wild-type strain BY4741 MATα, his3Δ1, leu2Δ0, met15Δ0, ura3Δ0 (Euroscarf), and the isogenic knockout Δpop2Δ and Δccr4Δ. Δpop2Δ was from the YKO library (OpenBiosystems) and Δccr4Δ was generated by substituting the target gene for a KanMX cassette using homologous recombination in the same genetic background (Longtine et al. 1998). The rpb1Δ-1 (rpb1Δ-G1437D) strain and isogenic wild-type strain were generated in our lab. Plasmids pRS316-RPO21, pRS315-RPO21, and pRS315-rpb1Δ-1 were generated by cloning the respective ORF or mutant ORF plus sequences 500 bp upstream and 250 bp downstream into pRS316 (ATCC) and pRS315 (ATCC) using Xhol/SacI restriction sites. The heterozygous RPO21/rop21Δ Sc yeast strain (BY4743, rop21::KanMX6/RPO21) was generated and transformed with pRS316-RPO21. Diploids were sporulated and tetrads dissected on YPD plates. After transformation of the shuffle strains with pRS315-RPO21 or pRS315-rpb1Δ-1, the resulting strains were streaked twice on 5-FOA plates and then on SC-Leu. Sp strain FY2317 h+, leu1-32::hENT1-leu1+ [pAH29] his7-366::hsv-tk::KanMX4 his7-366::hsv-tk::KanMX4 ura4-D18 ade6-M210 (Hodson et al. 2003) was kindly provided by Susan Forsburg. YPD medium was inoculated with a single Sc colony. Sp was grown in YES medium. The culture was grown to stationary phase overnight and diluted to OD_{500}=0.1. Measure points were taken every hour before OD_{500} reached 3. Additional time points were taken until stationary phase was reached. Doubling time was calculated by fitting the log-transformed values of OD_{500} into a linear function.

**Comparative dynamic transcriptome analysis (cDTA)**

Sc cells were grown in YPD medium overnight, diluted to an OD_{500} of 0.1, and grown to mid-log phase. OD_{500} of 0.8 corresponded to 1.75 × 10^7 cells per mL. 4-thiouracil (4[U], Sigma, 2 M in DMSO) was added to the media at a final concentration of 5 mM, and cells were harvested after 6 min of labeling by centrifugation at 2465g and 30°C for 1 min. The supernatant was discarded and the pellet resuspended in RNAlater solution (Ambion/Applied Biosystems). The cell concentration was determined by Cellometer N10 (Nexus). The transcription rate estimates resulting from both alternatives (Supplemental Methods S9). Between-array normalization of arrays containing mixed Sc and Sp total RNA was done by proportional rescaling, such that the median Sp gene expression level was 1 (Fig. 3B). Accordingly, between-array normalization of arrays containing mixed Sc and Sp labeled RNA was done by proportionally scaling the array to a median-labeled Sp gene expression level of 0 (Fig. 3A). The constant c scales the median half-life of all experiments. We calibrated c in a way that the resulting median Sc wild-type mRNA half-life equaled that observed previously (Miller et al. 2011). Now, all Sc RNA levels, no matter whether total or labeled, no matter from which experiment, can be compared on an absolute level. Decay rates and synthesis rates were obtained as described (Miller et al. 2011; Supplemental Methods S9). We assume that the labeled RNA fraction is subject to degradation from the very time it is synthesized. In contrast, Rabani et al. 2011 (see Supplemental Methods therein) assume that the labeled RNA fraction is mostly nuclear and not degraded at all. We compared the synthesis rate estimates resulting from both approaches (Supplemental Methods S9). Given our labeling time, the differences of both approaches are negligible. The whole analysis workflow has been carried out using the open source R/Bioconductor package DTA (Schwalb et al. 2012).

**Calculation of 4tU incorporation efficiency**

The metabolic labeling efficiency p_{lab} is defined as p_{lab}=p_{inc}/p_{cap}, the product of the incorporation efficiency p_{inc} (the probability of 4tU for being incorporated into an RNA transcript instead of a uridine) and the capture efficiency p_{cap} (the probability of a 4tU incorporation data analysis**

Data was preprocessed arraywise using expresso (R/Bioconductor) with the RNA background correction method. We created our own probe annotation environment (edf), which excludes probes in probesets that show cross-hybridization between Sc and Sp. A total of 8708 annotated Sc probes and 13,317 annotated Sp probes out of a total of 120,855 probes showed cross-hybridization when a conservative intensity cut-off of 4.5 (log intensity values after preprocessing) was used. Cross-hybridizing probes were excluded from further analysis. This included 16 whole probe sets (Fig. 2A; see Supplemental Fig. S1). Note that the standard GC-RMA method is not suitable for our purposes since its bias model cannot handle bimodal intensity distributions, as caused by the simultaneous hybridization of Sc and Sp transcripts with global differences in RNA abundance (Fig. 2B). Labeling bias estimation and correction was done as described (Miller et al. 2011) (Supplemental Methods S9). Between-array normalization of arrays containing mixed Sc and Sp total RNA was done by proportional rescaling, such that the median Sc gene expression level was 1 (Fig. 3B).
nucleotide inside an RNA for being biotinylated, captured, and recovered from streptavidin beads. A labeling efficiency substantially below 1 introduces a uridine-dependent labeling bias by letting newly transcribed, uridine-poor RNA have a higher probability to escape labeling. All of these efficiencies are of experiment-and strain-specific quantities. Only $p_{lab}$ can be estimated directly from cDTA data (Supplemental Method S10). We can use cDTA to conclude from $p_{lab}$ to the relative incorporation efficiencies by the equation
\[
P_{lab} (x, Sc) = \frac{p_{lab} (x, Sc)}{p_{lab} (x, Sp) ^ {1/1 - \frac{p_{lab} (y, Sc)}{p_{lab} (y, Sp)}}}.
\]

RT-qPCR

Sp and Sc cells were grown to $OD_{600} = 0.8$, harvested, and flash-frozen in liquid nitrogen. Cells were counted and mixed at 1:1 and 10:1 ratios. Total RNA was extracted, and the mRNA levels of Sc genes ACT1(YFL039C), ADH1(YOL066C), HIS4(YCL030C), and RDN1 (rRNA locus) and Sp genes GDI1(SPA2C221H10.12c) and GDP1(SPB2C215.05) were determined by RT-qPCR. RT-qPCR was carried out as described (Miller et al. 2011). A total of 500 ng of RNA was used to reverse transcribe cDNA using the iScript cDNA Synthesis Kit (BioRad). Primers were designed with the ProbeFinder online tool (http://qpcr.probefinder.com/organism.jsp, Roche Applied Science). The primer-pair efficiency was tested individually and ranged between 97% and 100%. PCR reactions contained 1 μL of DNA template, 2 μL of 10 μM primer pairs, and 12.5 μL of SsoFast EvaGreen Supermix (BioRad). qPCR was performed on a Bio-Rad CFX96 Real-Time System (Bio-Rad Laboratories, Inc.) using a 30-sec denaturing step at 95°C, followed by 40 cycles of 1 sec at 95°C, 4 sec at 63°C. Data analysis was performed with the software Bio-Rad CFX Manager 1.6.

Kinetic model

Our model has been cast as Equation (1) provided in the main text. The steady-state mRNA levels predicted by this model are $x = \frac{f(s')}{f(s)} x_0$, from which we deduce that regulation imposed by $S$ or $D$ is always global, i.e., total mRNA levels are shifted by a common factor $f(s')/f(s)$. Since the mRNA levels in the deadenylation mutants globally increase, we conclude that the mRNA level $s'$ of $D$ in the deadenylation mutants is higher than in wild-type (level s). At the same time, we can estimate the quotient $K_{synthesis}(S)/K_{synthesis}(R)$ by
\[
K_{synthesis}(S) = \text{median} \left( \frac{\text{synthesis rate of } g \text{ in the mutant}}{\text{synthesis rate of } g \text{ in the wildtype}} \right) \forall g \in \text{genes}
\]

(see Supplemental Fig. S8 for a rigorous derivation). Together, $s' > s$ and $f(s') < f(s)$ imply that $f$ acts as a transcription inhibitor. Similar considerations show that $d = a$ holds in the Pol II mutant, and that
\[
h(d) = \frac{\text{total mRNA mutant}}{\text{total mRNA wildtype}} \cdot \text{median} \left( \frac{\text{decay rate of } g \text{ in the mutant}}{\text{decay rate of } g \text{ in the wildtype}} \right) \forall g \in \text{genes} = 0.31 < 1.
\]

From $d = a$ and $h(d) < h(d)$ we conclude that $D$ is a degradation enhancer.

Data access

Microarray data were deposited in ArrayExpress (http://www.ebi.ac.uk/arrayexpress/) under accession number E-MTAB-760.

Acknowledgments

We thank the members of the Tresch and Cramer laboratories. We thank Dr. Elisabeth Lehmann for generating the heterozygote shuffle strain RPO21/rpo21. A.T. was supported by the LMUexcellent guest professorship “Computational Biochemistry.” P.C. was supported by the Deutsche Forschungsgemeinschaft, SFB646, TR5, FOR1068, NIM, the European Molecular Biology Organization (EMBO), an Advanced Investigator Grant of the European Research Council, a LMUexcellent research professorship “Molecular systems biology of gene regulation,” the LMAinnovativ projekt Bioimaging Network (BIN), and the Jung-Stiftung.

Author contributions: M. Sun, B.S., L.L., and P.C. conceived and designed the study. M. Sun and D.S. implemented and evaluated experimental methods. S.E. and M. Seizl conducted the rpb1-1 experiments. B.S. and A.T. designed and carried out computational analyses. M.S., D.S., N.P., K.M., S.E., and M. Seizl designed and performed experiments. P.C. and A.T. wrote the manuscript, with input from all authors. M. Sun, B.S., and D.S. contributed equally.
