Featured Application: The preliminary findings presented in this paper are expected to serve as a foundation for future studies investigating fall prevention in older adults.

Abstract: Previous studies have reported that vibrotactile stimulation of the nail of the hallux decreases the variability of the center-of-mass (CoM) movement in the lateral direction in subjects performing unsteady walking on the spot. This study investigated the effect of vibrotactile stimulation of the nail of the hallux on the CoM movement during walking. Healthy young males were asked to walk with and without stimulation, and their CoM was measured. The intrasubject mean and coefficient of variation (CV) of their walking speed, stance time, and CoM movement were evaluated. The differences between the variables with and without stimulation were determined, and the baseline-dependent effects of the stimulation on these variables were analyzed. It was observed that stimulation had a negative baseline-dependent effect on the CVs of the walking speed, stance time, and the CoM movement in the lateral direction. In particular, stimulation decreased the CV of the CoM movement in the lateral direction for subjects with a greater variability. Vibrotactile stimulation of the nail of the hallux can reduce the variability of the lateral displacement of the CoM movement in healthy young subjects who otherwise show a large variability of the CoM movement during walking without stimulation.

1. Introduction

During human walking, plantar tactile sensation provides somatosensory inputs to the central nervous system as feedback from the plantar surface, thereby making it easier to control balance and walking speed. A temporary reduction in these inputs reduces the walking speed [1] and increases the variability of temporal parameters and lumbar acceleration [2]. In addition, joint kinematics, muscle activity [3,4], and pressure distribution patterns [5] change during walking. Therefore, older adults suffering from sensory deficits caused by diabetic neuropathy have a lower walking speed and greater gait variability than healthy older adults [6].

Vibrotactile stimulation can augment somatosensory feedback during walking. Previous studies found that vibrotactile stimulation could change the stride-to-stride variability of the step width and stride length in the elderly [7], increase the walking speed, single-limb support time, and step length, and significantly decrease the cadence in stroke subjects [8]. In particular, the effect of vibrotactile
stimulation on the plantar surface is affected by the values obtained without stimulation at the baseline [9]. Thus, this stimulation method provides a baseline-dependent reduction in gait variability for subjects with a more unsteady gait. Vibrotactile stimulation-based interventions could improve walking instability in subjects with sensory deficits.

Previous studies used vibrators embedded at the bottom of insoles or shoes to stimulate the plantar surface [7–10]. Because these devices are integrated in shoes, users have to wear them to be stimulated. However, the plantar skin is thick; therefore, a relatively large stimulation strength is required to transmit vibrations. Furthermore, vibrators cannot be used when walking barefoot and the sensory input from the ground is blocked by the shoe sole and vibrator.

To overcome these problems, Sakai et al. [11–13] proposed a method to generate somatosensory inputs by stimulating the nail of the hallux. Toes have a particularly high distribution density of mechanoreceptors in the plantar region [14]. In addition, the transmission efficiency of vibration is high because a nail is harder than the skin. This method supports daily walking without blocking information from the plantar surface, unlike the technique in which a vibrator is embedded at the bottom of insoles or shoes. In previous studies [11–13], the vibrotactile stimulation of the nail of the hallux increased the stability of the center-of-mass (CoM) movement while walking on a spot by enhancing the tactile sensation experienced by the foot in healthy young males. On the other hand, one never moves forward while walking on the spot, and it is rarely practiced in daily living. Therefore, it is necessary to verify the effect of vibrotactile stimulation of the nail of the hallux during walking, which is the most frequently performed activity in daily living. However, there are no studies on the effect of the vibrotactile stimulation method on the CoM movement during walking.

The CoM is a theoretical point through which the force of gravity acts on an object [15], and it controls the imbalance and the risk of falls in the elderly [16]. Previous studies investigated the effect of the vibrotactile stimuli on the gait performance, that is, walking speed, cadence, and step length [7–10]. However, the effect of vibrotactile stimulation on the CoM movement is still unclear. If the effect of intervention as a result of using this novel method on the CoM movement during walking is clarified, it can be applied to people with unstable CoM movement, such as older adults and patients with hemiplegia.

This study investigated whether the vibrotactile stimulation of the nail of the hallux affects the CoM movement during walking. A previous study found that vibrotactile stimulation of the plantar surface had a baseline-dependent effect on gait variability and resulted in a greater decrease in variability in subjects with greater baseline variability [9]. We hypothesized that the previous findings of walking on the spot [11–13] are also applicable to walking; in other words, among healthy young people, vibrotactile stimulation of the nail of the hallux is more effective in subjects with a large variability of the CoM movement during walking.

2. Materials and Methods

2.1. Participants

Thirteen healthy young males (age: 23.8 ± 1.9 years, height: 1.69 ± 0.03 m, weight: 63.9 ± 7.4 kg, body mass index: 22.1 ± 2.6 kg/m²) participated in this study. None of the subjects had any history of neuromuscular diseases, trauma, or orthopedic diseases. The dominant leg was determined using the method reported by Schneiders et al. [17], and all the participants in this study were found to be right leg dominant. This study was conducted according to the Declaration of Helsinki [18], and the experimental protocol was approved by the local institutional review board. All the participants gave their written informed consent before the measurements.

2.2. Vibration System

Figure 1 shows the vibration system used in this study. The system consists of a vibrator (LD14-002; Nidec Copal Corporation, Tokyo, Japan), a microcontroller (mbed LPC11U24FHI33/301;
NXP Semiconductors, Eindhoven, the Netherlands), and a pressure sensor (FSR 400 Short; Interlink Electronics, Camarillo, CA, USA). The vibrator was driven using a haptic motor driver (DRV2605; Texas Instruments, Dallas, TX, USA) connected to the microcontroller. When the pressure sensor detects the ground contact of the hallux ball, a sine wave with a frequency of 150 Hz is immediately generated with negligible time delay. The vibration amplitude was changed using the graphical user interface of a custom-made application running on a Windows tablet.

![Vibration system used in this study.](image1)

**Figure 1.** Vibration system used in this study. The vibrator, pressure sensor, and microcontroller were attached on the nail of the hallux, hallux ball, and distal end of the shank, respectively. The vibration was controlled through the graphical user interface of a custom-made application running on a Windows tablet.

2.3. **Experimental Setup**

Fifty-seven infrared reflective markers were placed bilaterally over bony landmarks to measure full-body motion in accordance with a previous study [19]. The vibrators were attached to the both sides of the nail of the hallux using double-sided tape because the hallux is the largest toe of the foot, and the subject could perceive a tactile sensation on the finger pad when this nail was stimulated using vibration [11–13]. The pressure sensors were placed under the hallux ball, and the microcontrollers were attached to the distal end of the shank using a rubber band.

2.4. **Data Collection**

Measurements were recorded in a laboratory with a straight 10-m walkway. A three-dimensional motion analysis system with 15 infrared cameras (Vicon MX and Vicon T, Vicon Motion Systems, Oxford, UK) and nine force plates (BP400600-2000PT, AMTI, Watertown, MA, USA) were used to record the kinematic and kinetic data at sampling frequencies of 200 Hz and 1000 Hz, respectively (Figure 2).

![Schematic diagram of a subject during walking and recording of kinematic and kinetic data using a 15-camera motion capture system and nine force plates.](image2)

**Figure 2.** Schematic diagram of a subject during walking and recording of kinematic and kinetic data using a 15-camera motion capture system and nine force plates.
During the walking trials, all the participants were asked to walk barefoot at a comfortable speed. The participants walked with and without vibrotactile stimulation. The orders of these walking conditions were randomized. The vibration amplitude was adjusted to be as weak as possible so that it was just perceivable to each subject on the finger pad contacting the surface while walking because each individual has a different sensation of the vibration. Before the measurements, the participants walked along the walkway for a few minutes to get accustomed to the environment. Subsequently, five successful trials were conducted where each participant accurately stepped on a force plate.

2.5. Data Analysis

The CoM position was calculated using DhaibaWorks—our self-developed motion analysis software [20]. The full-body motion was reconstructed by fitting the marker trajectories and individual body model using a link structure. The dimensions of the body model were estimated statistically using the height and weight of the participant based on a database of Japanese body dimensions [20]. The CoM data were digitally filtered using a fourth-order Butterworth low-pass filter with a cut-off frequency of 10 Hz. The CoM movement during the stance phase of the right limb was extracted based on the ground reaction force data. The amplitudes of the CoM movement in the vertical, progression, and lateral directions during the stance phase were calculated. The walking speed was calculated from the CoM movement in the progression direction of the CoM and the time taken during the stance phase.

The intrasubject mean and standard deviation (SD) values were calculated during the stance phase. Next, the coefficient of variation (CV = (SD/mean) × 100) was calculated as an index of intrasubject variability [21]. The differences between the mean and CV values of the variables obtained with and without stimulation were determined as the effect of stimulation. In addition, to examine the impact of a measurement error, we calculated the minimal detectable change (MDC). The MDC indicates the minimal amount of change that is not likely to be considered a change due to an accidental error in measurement [22,23]. First, the standard error of measurement (SEM) was calculated using the SD and intraclass correlation coefficient. Subsequently, the MDC was calculated using the relation: SEM × 1.96 × √2 [22]. Low-pass filtering and calculation of these variables were performed using MATLAB R2019a (MathWorks Inc., Natick, MA, USA).

2.6. Statistics

We conducted the Shapiro–Wilk test to verify normality assumption. Subsequently, because the sample size was small, the differences between the mean and CV values of the CoM movement of the variables obtained with and without stimulation were analyzed by conducting the Wilcoxon signed rank tests, which are nonparametric tests used to analyze the matched-pair data [24]. The baseline-dependent effects of the stimulation were determined by performing the linear regression analysis, and curve regression analysis in case of non-normality. If the relationship between the baseline values and the effect of the stimulation became significant, an additional subgroup analysis was performed. Next, the subjects were divided into two groups based on the value obtained when walking without stimulation—a steady group consisting of six subjects with a small variability, and an unsteady group consisting of six subjects with a large variability, excluding the subject with the median value. Subsequently, the Wilcoxon signed rank test was conducted to examine the difference between the variables obtained with and without stimulation in each group. Values with \( p < 0.05 \) were considered to be statistically significant. All the data were analyzed using SPSS Statistics version 25 (SPSS Inc., Chicago, IL, USA).

3. Results

3.1. Differences Between Variables Obtained with and Without Stimulation

Table 1 presents the comparison results of the variables obtained with and without stimulation. The walking speed decreased by 3%, and the CoM movement in the progression direction decreased by
2% with vibrotactile stimulation compared with the corresponding values obtained without stimulation. These differences are smaller than the MDC value of each variable. Significant differences were not observed in the values of other variables obtained with and without stimulation.

**Table 1.** Comparison of variables obtained with and without stimulation (stim).

| Variable                  | Without Stim | With Stim | MDC | P-Value |
|---------------------------|--------------|-----------|-----|---------|
| Mean                      |              |           |     |         |
| Walking speed (m/s)       | 1.32 ± 0.15  | 1.29 ± 0.14 | 0.10 | 0.03 * |
| Stance time (s)           | 0.61 ± 0.05  | 0.61 ± 0.05 | 0.03 | 0.38   |
| CoM (cm)                  |              |           |     |         |
| Vertical                  | 92.66 ± 2.49 | 92.65 ± 2.46 | 1.06 | 0.97   |
| Progression               | 81.22 ± 6.93 | 79.42 ± 7.54 | 5.69 | 0.02 * |
| Lateral                   | 1.92 ± 0.67  | 1.75 ± 0.73 | 2.17 | 0.97   |
| CV (%)                    |              |           |     |         |
| Walking speed             | 2.69 ± 1.28  | 3.37 ± 1.65 | 0.38 |         |
| Stance time               | 1.84 ± 0.76  | 2.39 ± 1.12 | 0.15 |         |
| CoM                       |              |           |     |         |
| Vertical                  | 0.35 ± 0.20  | 0.36 ± 0.25 | 0.86 |         |
| Progression               | 2.48 ± 0.95  | 2.61 ± 1.40 | 0.75 |         |
| Lateral                   | 35.69 ± 13.00 | 32.16 ± 9.81 | 0.38 |         |

Values: Mean ± standard deviation. MDC: Minimal detectable change. *: Statistically significant difference between values with and without stimulation ($p < 0.05$).

3.2. Baseline-Dependent Effect of Vibrotactile Stimulation

In terms of the mean value, although the CoM movements in the progression and lateral directions were analyzed by performing the curve regression analysis and the linear regression analysis, the results of the curve regression analysis were not statistically significant ($p = 0.898$ and $0.158$, respectively). Therefore, only the linear regression analysis results are presented in Table 2 and Figure 3. The effect of stimulation on the CV values of the walking speed, stance time, and CoM movement in the lateral direction depends on the CV values obtained when walking without the stimulation. The negative baseline-dependent effect of these variables indicates that the differences between the CV values decreased linearly as the values of the variable increased. Therefore, the subjects were divided into the steady and unsteady groups for each of these variables, and the subjects in these group were different depending on each variable. A comparison of the results of these groups indicates that the CV values of the walking speed and stance time increased in the steady group as a result of stimulation, as shown in Figure 4a,b, respectively. On the other hand, the CV of the CoM movement in the lateral direction decreased in the unsteady group (Figure 4c).

**Table 2.** Linear regression analysis results showing the effects of values obtained without stimulation and changes in values due to stimulation.

| Variable                  | Unstandardized Coefficients (95% CI) | Standardized Coefficients | Adjusted R² | P-Value |
|---------------------------|--------------------------------------|---------------------------|-------------|---------|
| Mean                      |                                       |                           |             |         |
| Walking speed             | −0.10 (−0.36 to 0.15)                | −0.27                     | 0.01        | 0.38    |
| Stance time               | −0.01 (−0.22 to 0.18)                | −0.06                     | 0.08        | 0.84    |
| CoM                       |                                       |                           |             |         |
| Vertical                  | −0.02 (−0.09 to 0.05)                | −0.18                     | 0.05        | 0.56    |
| Progression               | −0.02 (−0.34 to 0.29)                | −0.05                     | 0.08        | 0.84    |

4. Discussion

This study examined the effect of vibrotactile stimulation of the nail of the hallux on the CoM movement during the stance phase. The proposed method had a baseline-dependent effect on the variability of the CoM movement and was more effective for subjects with a large variability of the CoM movement in the lateral direction during walking. Stimulation did not affect the amplitude of the CoM movement. These results support our hypothesis. This study highlighted the effect of the novel method in which vibrotactile stimulation was applied to the nail of the hallux to the variability of the CoM movement during walking in healthy young people.

As shown in Figure 3, the effect of vibrotactile stimulation of the nail of the hallux depends on the variability of the walking speed, stance time, and the CoM movement in the lateral direction at the baseline. Stimulation decreased the fluctuations in these variables for subjects exhibiting a large intrasubject variability when walking without the stimulation. This result is in good agreement with that of a previous study that examined the effect of stimulation of the plantar surface [9]. In particular, stimulation was remarkably effective for subjects with a large variability of the CoM movement in the lateral direction (Figure 4c). The CoM movement in the lateral direction is associated with walking stability [15,25]. In addition, a large walking variability is considered indicative of poor walking stability [26]. The lateral movement of walking was actively controlled using the feedback control [27]. We speculated that vibrotactile stimulation of the nail of the hallux could enhance the tactile sensation perceived by the foot. In addition, the stimulation was likely to put the attention of the participant on the foot by suprathreshold stimulation. Attention has an impact on the control of non-automated motion [28]. Therefore, by using this stimulation method, the CoM movement in the lateral direction during walking was stabilized for subjects with unsteady movement, in the same manner as in previous studies that achieved stabilization while walking on the spot [11–13]. In previous studies [6,29,30], older adults were found to have greater walking variability during walking compared to young people. Thus, vibrotactile stimulation of the nail of the hallux might be useful in reducing the variability of the CoM movement in the elderly.

In contrast, stimulation increased the variabilities of the walking speed and stance time in the steady group, as shown in Figure 4a,b, respectively. The sensory feedback from the foot contributes to the cyclical gait patterns produced by neural rhythm generators in the central nervous system [31]. We speculated that the feedback system of the subject in the steady group was already working when walking without stimulation. However, by applying the stimulation to such a subject using vibration, the cyclical gait patterns may be disrupted. Therefore, the variabilities of these variables, including the temporal aspect of gait, increased in the steady group as a result of stimulation.

The walking speed decreased with the CoM movement in the progression direction because of the stimulation (Table 1). However, the values of these variables decreased by only a few percent and were smaller than the MDC values in this study. The MDC is the minimal amount of change that is not likely to be considered a change due to a measurement error [22]. Thus, these differences were caused by a measurement error and were not sufficient to show the effect of stimulation. Consequently, vibrotactile stimulation did not affect the amount of the CoM movement during walking in healthy young people. These results suggest that the vibrotactile stimulation of the nail of the hallux is more likely to affect the variability of the CoM movement than with the amount of the CoM movement.

The present study also has some limitations. First, a relatively small sample size of young people was considered, based on the before–after design. Therefore, to clarify the effect of this stimulation method on walking stability in the elderly, further studies should be conducted using a randomized controlled trial with a larger sample size, including older adults. Second, a previous study reported that there are gender differences in biomechanical gait parameters [32]. Therefore, only male participants were considered in this study to eliminate the effects of gender differences. To elucidate the gender-specific effect, further studies are necessary to examine the effect of this stimulation method on walking in female subjects during walking. Third, the stimulation amplitude was set to a suprathreshold level and was adjusted to be as weak as possible by tuning it for each subject.
The differences in the magnitude and frequency of vibration, including supra- and subthreshold values, affected the stride-to-stride fluctuations in the stride length and interval [10]. In addition, no consensus was reached on the effect of the differences between vibrating devices or the duration and magnitude of the stimulation on gait parameters [33]. In particular, older adults have an age-related decline in the sensorimotor and/or cognitive function [6]. In a future study, we intend to investigate the optimal setting of the vibration applied to the nail of the hallux considering the age of the subjects. Furthermore, in this study, the effectiveness of the proposed method could not be compared with that of the conventional method that stimulated the plantar surface because the subjects may feel uncomfortable while attaching the vibrator to the plantar skin and walking barefoot. In the future, we will consider fabricating shoes for the experiments to avoid discomfort and to compare the effects of both the proposed and the conventional methods. Finally, the lateral control of walking was achieved using hip abductor muscles [34]. Analysis of the kinetics and muscle activity of this muscle may be useful to verify the effect of the vibration stimulation on the lateral displacement of the CoM.

5. Conclusions

This study examined the effect of vibrotactile stimulation of the nail of the hallux on the CoM movement during walking in young people. Stimulation of the nail of the hallux had baseline-dependent effects on the variability of the walking speed, stance time, and the CoM movement in the lateral direction during the stance phase. Among healthy young males, the proposed stimulation method was more effective in those with a large variability of the CoM movement in the lateral direction during walking. These preliminary findings can serve as a foundation for future studies on the variability of gait in older adults. Further studies are required to clarify the effect of the proposed stimulation method on the walking stability in older adults.
