Abstract

Pulmonary artery dissection is a rare and lethal condition. Few cases are reported in the literature, and most are
derived from autopsies. In most cases, pulmonary artery dissection is a complication of chronic pulmonary hypertension
leading to pulmonary artery aneurysm but there are other causes. We describe a case of iatrogenic pulmonary artery
dissection in an elderly patient with ostium secundum defect. In particular, we describe the role of cardiac magnetic
resonance in making this diagnosis and guiding future therapeutic decisions.

Keywords: Cardiac magnetic resonance, Ostium secundum defect, Pulmonary dissection, Pulmonary hypertension

1. Introduction

Pulmonary artery (PA) dissection is a rare and lethal condition. Few cases are reported in the literature, and most are
discovered from autopsies. In most cases, PA dissection is a complication from chronic pulmonary hypertension
leading to a PA aneurysm [1–3]. Other cases of reported PA dissection are caused by an extension of a chronic type
A aortic dissection through a patent ductus arteriosus or such as a Takayasu’s arteritis complication without pulmonary
arterial hypertension (PAH) [4,5]. In effect, PA dissection can also occur rarely in the absence of PAH [6].
Cases of PA dissection are also reported in patients with congenital heart disease such as patent ductus arteriosus and
Eisenmenger’s syndrome [7,8].

Liu et al. [9] reported a case of a full-length PA dissection in a young patient with idiopathic PAH who requested
conservative treatment with PAH-specific therapy after refusing heart–lung transplantation, the treatment recommended in extended
PA dissection.

However, currently there are no management guidelines for PA dissection, despite the fact that PA
dissection has a mortality rate of 80% within a few hours of diagnosis.

Senbaklavaci et al. [3] reported that patients with PA dissection should undergo surgery, including patients with chronic PA dissection without PAH. Li et al. [10] reported that for stable, asymptomatic
patients, conservative treatment and follow-up are necessary and that further dilatation of the PA is an
indication for surgery.

It is probable that, given the high risk of mortality associated with PA dissection, the treatment with the
best results is surgical repair, but in patients who refuse surgical treatment or when a comorbidity implies high surgical risk, conservative medical treatment should be considered. The experience with conservative medical management using
vasodilator therapy is limited to a very small number of patients, reporting favorable results [11].
Diagnosis of PA dissection is not always easy. Patients can have dyspnea or oppressive retrosternal chest pain. Echocardiography, computed tomography (CT), and cardiac magnetic resonance (CMR) can help facilitate a correct diagnosis.

In this case, we describe an iatrogenic PA dissection that was discovered 2 days after a right heart catheterization in a patient with ostium secundum interatrial septum defect (ISD) and PAH. However, regardless of etiology, PA dissection predisposes to sudden cardiac death and cardiogenic shock, and it requires an immediate diagnosis and treatment. Management of this condition is not always easy.

2. Case report

An 81-year-old man with progressive dyspnea and recent diagnosis of ostium secundum ISD with PAH was admitted to our hospital for assessment of PAH and evaluation of the possibility of percutaneous closure of ISD. At hospital admission, the patient presented with a blood pressure of 100/70 mmHg, arrhythmic heart auscultation, and mild cyanosis with arterial oxygen saturation of 86% without oxygen therapy. His electrocardiogram (ECG) showed known atrial fibrillation. His CMR scan revealed a large thrombosed dissection of right PA. Steady-state free precession (SSFP) images showed main and right PA dilatation, right PA lumen reduction that is compressed by hypodense mass and a thrombosed false lumen (Fig. 1a). Contrast enhanced-magnetic resonance angiography (CE-MRA) showed a right PA perfusion defect (Fig. 1b).

Chest CT was performed to confirm the data. The CT scan showed thrombosed right PA dissection (Fig. 1c). CT images demonstrated hypodense formation at the right PA bifurcation, and this formation was not enhanced in the angiography and venous phase images (Fig. 1d). For the most part, during the venous phase, a small flap appeared in the lumen vessel at the interlobar tract level.

Upon confirmation of the presence of PA dissection, a surgery consultation was requested. Considering the comorbidity, high surgical risk, and hemodynamic stability, the determined appropriate course of action was regular follow-up and medical therapy. Thus, the patient continued his therapy with diuretic and sildenafil for pulmonary hypertension, beta-blockers and heparin for atrial fibrillation, and oxygen therapy with subsequent mild improvement of dyspnea. The patient improved and was discharged; he was clinically stable and asymptomatic 1 month after the optimized medical treatment. CT was repeated after 1 month and showed that the right PA filling defect had slightly increased. Three months after discharge, the patient died at home because of comorbidity.

3. Discussion

In our case, the pre-existent PAH and PA dilatation facilitated iatrogenic dissection (a rare complication of PAH and pulmonary dilation in association with rupture of the vessel). It is probable that balloon inflation during Swan–Ganz catheterization caused PA dissection in a dilated and frail vessel, which led to the development of a future acute event. In effect, the majority of PA dissections occur...
in the presence of medial degeneration with fragmentation of elastic fibers and generalized dilatation of the pulmonary arterial tree caused by chronic PAH. PA dissection is not predictable. Perhaps, as suggested in reviews, severe dilatation of the PA, high PA pressure, or a rapid change in diameter (2.0 and 2.5 cm/y) and pressure (40 mmHg/y) should warrant further evaluation or management to preclude a catastrophic event [12].

In addition, in consideration of the high surgery risk and the patient’s comorbidity, conservative medical treatment was performed. The patient’s death after 3 months confirmed the difficult therapeutic decision in an elderly patient with multiple comorbidity and high-risk surgery.

Chest CT and CMR have more advantages in the diagnosis of PA dissection compared with echocardiography. Echocardiography is unable to show PA dissection if the dissection is not proximal and if the acoustic window is not good. Chest CT with pulmonary angiography allows a better definition of the presence and extension of dissection in the main pulmonary trunk and the main branch. Moreover, although CMR allows an accurate diagnosis of PA dissection, CT with pulmonary angiography is superior to CMR in the evaluation of the peripheral pulmonary circulation.

4. Conclusion

Management of PA dissection is not always easy even if it requires immediate diagnosis and surgical repair. Chest CT is the gold standard in the diagnosis of PA dissection even though multimodality CMR can be used to make the diagnosis by providing important data. In this patient, considering the cause and characteristics of dissection, hemodynamic stability, and high surgical risk, the appropriate decision was to use conservative medical therapy and proceed with regular follow-up using chest CT. In addition, for immediate diagnosis and treatment of patients with PAH, ingravescent dyspnea, and chest pain, clinicians should consider PA dissection.
