(Dated: May 15, 2020)

We report on a search for elementary particles with charges much smaller than the electron charge using a data sample of proton-proton collisions provided by the CERN Large Hadron Collider in 2018, corresponding to an integrated luminosity of 37.5 fb$^{-1}$ at a center-of-mass energy of 13 TeV. A prototype scintillator-based detector is deployed to conduct the first search at a hadron collider sensitive to particles with charges $\leq 0.1e$. The existence of new particles with masses between 20 and 4700 MeV is excluded at 95% confidence level for charges between 0.006e and 0.3e, depending on their mass. New sensitivity is achieved for masses larger than 700 MeV.

I. INTRODUCTION

Over a quarter of the mass-energy of the Universe is widely thought to be some kind of nonluminous “dark” matter (DM), however, all experiments to date have failed to confirm its existence as a particle, much less its properties. The possibility that DM is not a single particle, but rather a diverse set of particles with as complex a structure in their sector as normal matter, has grown in prominence in the past decade, beginning with attempts to explain observations in high-energy astrophysics experiments [1][2].

Many experimental efforts have been launched to look for signs of a dark sector, including searches at high-energy colliders, explorations at low-energy colliders, precision tests, and effects in DM direct detection experiments (for recent reviews see Refs. [3][5]). Most of these experiments target the dark sector via a massive dark photon, in what we refer to as the “Okun phase”[6][7]. An alternative assumption, which we call the “Holdom phase”[7][8], results in massless dark photons. In these models the principal physical effect is that new dark sector particles that couple to the dark photon will have a small effective electric charge. These are generically called millicharged particles since a natural value for their electric charge of $Q \sim \alpha e/\pi$ arises from one-loop effects [9]. In this paper we use the symbol $\chi$ to denote a millicharged particle. For a given mass and charge, the pair production of millicharged particles at the CERN Large Hadron Collider (LHC) is almost model independent. Every standard model (SM) process that results in dilepton pairs through a virtual photon would, if kinematically allowed, also produce $\chi^+\chi^-$ pairs with a cross section reduced by a factor of $(Q/e)^2$ and by mass-dependent factors that are well understood. Millicharged particles can also be produced through Z boson couplings that depend on their hypercharge [7].

Previous experiments have searched for millicharged particles [10][16]. The parameter space spanned by the mass and charge of $\chi$ is also constrained by indirect observations from astrophysical systems [9][15][17][20], the cosmic microwave background (CMB) [21], big-bang nucleosynthesis [22], and universe overclosure bounds [17]. While direct searches robustly constrain the parameter space of millicharged particles, indirect observations can be evaded by adding extra degrees of freedom, which can readily occur in minimally extended dark sector models [7]. In particular, the parameter space $1 < m_\chi < 100$ GeV, an ideal mass range for production at the LHC, is largely unexplored by direct (or indirect) searches. Such a signature would not be detectable by the CMS and ATLAS experiments at the LHC [23][24], as all detector elements rely on the electromagnetic (EM) interaction of the millicharged particle with ordinary matter. For a
millicharged particle the interaction strength is reduced by a factor of $(Q/e)^2$ with respect to that of a particle of the same mass that has charge $e$. The detector signal is also reduced by the same factor, and is typically too small to be recorded by detectors designed for particles of charge $e$. The production of millicharged particles in collider experiments would result in events with missing transverse momentum, however, SM processes with neutrinos as well as instrumental effects tend to overwhelm their signatures. No searches for particles with $Q/e \lesssim 0.1e$. 

It is then clear that dedicated detectors are needed to search for millicharged particles at a hadron collider. In 2016, we discussed the possibility to build such a detector at the LHC, which we called milliQan [25], at the CMS experimental site and aligned with the CMS interaction point (IP). Since then we have installed and operated a small fraction of such a detector (“milliQan demonstrator”) to measure backgrounds and provide a proof of principle and feedback for the full detector design. In 2018, the demonstrator collected a data set of proton-proton (pp) interactions corresponding to an integrated luminosity of $37.5 \text{fb}^{-1}$, at a center-of-mass energy of $13 \text{TeV}$. This corresponds to $86\%$ of the total luminosity delivered by the LHC in the period the demonstrator was operational. While the demonstrator is only $\sim 1\%$ of the full milliQan, the data collected already provides competitive constraints on the existence of millicharged particles of mass $20$–$4700 \text{MeV}/c^2$ and $Q/e \sim 0.01$–$0.3$.

II. DETECTOR

A thick sensitive volume is required to be capable of observing the small energy deposition of a particle with $Q/e \lesssim 0.1e$. The milliQan demonstrator is, therefore, composed of three layers of $80 \times 5 \times 5 \text{cm}$ scintillator bar arrays pointing to the CMS IP, with each array consisting of three pairs of bars, stacked on a $3.6 \text{m}$ long rectangular aluminum tube, for a total of $18$ bars. We label the closest, middle and furthest layer from the CMS IP as layer 1, layer 2 and layer 3, respectively.

The milliQan demonstrator is located in an underground tunnel at a distance of $33 \text{m}$ from the CMS IP, with $17 \text{m}$ of rock between the CMS IP and the demonstrator that provides shielding from most particles produced in LHC collisions. In the CMS coordinate system [24], the detector is positioned at an azimuthal angle ($\phi$) of $43^\circ$ and pseudorapidity ($\eta$) of $0.1$. Diagrams of the detector’s position are shown in Fig. 1. Located $70 \text{m}$ underground, the muon flux from cosmic rays is reduced by a factor of $\sim 100$ compared to the surface. The detector is aligned using standard laser-based survey techniques such that the center of the scintillator array projects a line to within $1 \text{cm}$ of the CMS IP. This alignment is validated using muons produced at the CMS IP, as discussed in Section IV C.

In addition to the scintillator bars, additional components were installed to reduce or characterize certain types of backgrounds. Lead bricks are placed between the layers to prevent low-energy secondary particles from one layer from entering another layer. Four scintillator slabs are located along the length of the detector to tag throughgoing particles, provide time information, and shield the bars from neutron radiation. Thin scintillator panels cover the top and sides, providing the ability to reject cosmic muons. Lastly, hodoscopes consisting of $2 \times 2 \times 45 \text{cm}$ scintillator volumes are used to identify the tracks of beam and cosmic muons. A diagram of the detector components is shown in Fig. 2 and a photo-
A diagram of the detector components. The PMTs are not shown for the slabs or panels. All components are installed on an aluminum tube.

Scintillator light in the bars, panels, and slabs is detected by photomultiplier tubes (PMTs) coupled to the scintillator volumes. Three types of PMTs are used in order to test different manufacturers and gains: the Hamamatsu R878, Hamamatsu R7725, and Electron Tube 9814B. Analog signals from each PMT are sent to two 16-channel CAEN V1743 digitizers, operating at $1.6 \times 10^9$ samples per second with 12-bit resolution, providing 1024 samples within a 640 ns acquisition window. Each scintillator volume with a PMT attached is referred to as a “channel”. Since millicharged particles produced at the CMS IP would traverse the full length of the detector in $\mathcal{O}(10)$ ns, tight timing requirements allow for a significant reduction in combinatoric backgrounds by requiring the coincidence of in time signals in all layers, as described in Section V. The PMTs are powered by a CAEN SY5527 power supply system. The hodoscopes are readout with silicon photomultipliers. Their data are triggered and stored independently from the main data stream.

The data set analyzed for this search was collected during 2018, including periods with the LHC beam providing pp collisions (the “beam-on” data set) and periods with no collisions (the “beam-off” data set). The beam-off data set provides a statistically independent sample to study background processes. The detector is located in an area in the far fringe field of the CMS superconducting magnet, and both beam-on and beam-off data sets were recorded with the magnet at its nominal strength of 3.8 T. The actual magnetic field in the milliQan cavern is measured by magnetic field sensors installed in various positions around the detector. We find this magnetic field to be under 2 mT when the CMS magnet is at 3.8 T. Additional data samples were recorded with the field at 0 T for PMT calibration.

Data is collected by triggering on the coincidence of at least three channels (triple-coincidence) within a window of 100 ns. A bar contributes to this coincidence if it has a rising edge consistent with a single photoelectron threshold, and the panels and slabs contribute to the coincidence with more stringent thresholds appropriate for identification of muons from cosmic rays (“cosmic muons”) and muons from pp interactions (“beam muons”). The total trigger live-times were 1106 and 1042 hours for the beam-on and beam-off data sets, respectively. The average trigger rate was 14.4 Hz. Outside of the beam time, additional specialized runs were taken using single-channel and double-coincidence triggers, with different thresholds and operating voltage settings, in or-
order to collect data samples for calibrations and validation studies.

III. CALIBRATION

We first calibrate the size of the generated pulses in each channel, which requires a measurement of the average size of a pulse from a single photoelectron (SPE) in each PMT, as well as the mean number of photoelectrons \( \langle N_{PE} \rangle \) generated in each channel by a throughgoing muon. The former is strictly a property of each PMT, while the latter depends on each scintillator, its wrapping, its coupling to the PMT, and the PMT quantum efficiency.

The SPE calibration is performed in-situ by isolating pulses from late-arriving scintillation photons, which largely produce SPEs in the PMTs. The mean SPE area is then found by locating the peak of the resulting pulse area distribution. These measurements are cross-checked by bench measurements of SPE waveforms generated by a flashing LED, following the method outlined in Ref. [31]. In the following, the \( n_{pe} \) of a given pulse is defined as the pulse area divided by this per-channel SPE calibration, and represents an estimate of the true number of photoelectrons that generated the pulse.

For panels and slabs, the \( \langle N_{PE} \rangle \) calibration is performed directly based on throughgoing beam muons (slabs) and cosmic muons (panels). The measured average pulse area is scaled by the per-channel SPE measurement to calculate the mean number of photoelectrons generated by a beam or cosmic muon.

For the bars, a direct calibration is not possible as both beam and cosmic muons saturate the readout. Instead, we take an indirect approach, using the fact that the PMT response scales as a power law over a wide range of operating voltages. First, the mean areas of cosmic muon pulses are measured at 5–6 operating voltages, which are low enough to ensure that the PMT signals do not saturate. A power law function is then fit to these points, and extrapolated to the nominal operating voltage. Finally, this number is scaled by the per-channel SPE measurement to arrive at an estimate of the number of photoelectrons generated by a cosmic muon. The validity of the power law assumption is confirmed by separately fitting a power law function to the mean areas of SPE pulses over a range of voltages near the nominal operating voltage. The fitted exponent is found to be consistent with that from the fit to the cosmic muon pulse areas for all bars. The calibrated value of \( \langle N_{PE} \rangle \) for a beam muon traversing the full 80 cm length of a bar varies from 22,000 to 82,000; this means that \( \langle N_{PE} \rangle = 1 \) is expected in the bars for particles of charge \( Q/e \sim 0.004-0.007 \).

The dominant source of uncertainty in each bar’s \( \langle N_{PE} \rangle \) measurement is the statistical uncertainty from the power law fit and extrapolation, which is 10–20% depending on the channel, and is uncorrelated between channels. Smaller uncertainties, generally on the order of a few percent, come from differences in the residual magnetic field between calibration runs and data-taking runs; the effect of a low-pass filter applied to the waveforms; and differences between the in-situ and lab-based SPE measurements. These are correlated between bars with PMTs of the same type.

The timing of the PMTs must also be calibrated. The calibration procedure is designed such that a particle traveling near the speed of light through the detector from the CMS IP should have the same time value in every bar, panel and slab. This calibration is performed using both beam and cosmic muons. Figure 4 shows the time difference between a muon pulse in layer 3 compared to a muon pulse in layer 1, where the events have been categorized as either beam or cosmic muons based on the timing of the pulses in the slabs. The resolution in the time difference between layers is approximately 4 ns for beam muons which travel through the detector from the CMS IP. An additional correction is applied to account for the dependence of the timing of the pulses on their size. This correction is derived using secondary particles that result from the interactions of beam muons with the detector as they traverse it. The timing resolution degrades as the size of the pulses gets smaller; the resolution of the lowest \( n_{pe} \) pulses passing the selection outlined in Section II is \( \sim 15 \) ns. The modeling of the timing of these secondaries is used to derive a systematic uncertainty in the timing in simulation.

Using dedicated runs, the trigger efficiency is measured as a function of \( n_{pe} \) for each bar. This information is used to reweight the simulated samples of signals from millicharged particles described in Section IIIB. The trigger efficiency is measured to reach 100% for \( n_{pe} > \sim 2 \) for all channels.
IV. SIMULATION

A. Event generation

We generate pair-production of millicharged particles in 13 TeV pp collisions through the Drell-Yan process, as well as from $Y$, $J/\psi$, $\psi(2S)$, $\phi$, $\rho$, and $\omega$ decays into $\chi^+\chi^-$, and from Dalitz decays of $\pi^0$, $\eta$, $\eta'$, and $\omega$.

Drell-Yan events are generated assuming that $\chi$s are isospin singlet fermions, using the Lagrangian of Ref. 23 implemented in the MADGRAPH5_AMC@NLO 24 event generator, with a minimum invariant mass requirement on the millicharged pair of 2 GeV/c$^2$. Because of the limited integrated luminosity and the small size of the demonstrator, there is essentially no sensitivity to Drell-Yan production of millicharged particles in the data set discussed in this paper.

The production cross section and transverse momentum $p_T$ distribution of $J/\psi$ and $\psi(2S)$ in the central rapidity $y$ region is taken from calculations of charmonium production from direct processes 34–36 and from bottom hadron decays 37,38, including theoretical uncertainties. Theoretical calculations of bottomonium production 39 are not reliable at low transverse momentum ($p_T < 15$ GeV) 40, where most of the cross section lies. As a result, for $p_T > 20$ GeV we use the cross sections and $p_T$ spectra measured at a center-of-mass energy of 13 TeV 41, at lower $p_T$ we use measurements from 7 TeV data 42,43, rescaled using the measured ratio of 13 to 7 TeV cross sections at slightly higher rapidity ($2 < y < 2.5$) 44.

All relevant light flavor mesons except $\phi$ mesons are generated with the minimum bias PYTHIA8 generator 45 with the Monash 2013 tune 46. This is the tune that gives the best agreement with several measurements of light meson rates and $p_T$ spectra at the LHC, although in most cases at center-of-mass energies lower than 13 TeV 47,48. The Monte Carlo spectra for $\eta$ ($\rho$, $\omega$) with $p_T < 3$ (1) GeV are scaled down by factors as large as two, based on the experimental results cited above. On the other hand, the production of $\phi$ mesons is modeled with the minimum bias PYTHIA6 generator 49 with the DW tune 50, since this Monte Carlo setup best reproduces $\phi$ meson data 51. All PYTHIA Monte Carlo generations are normalized to a minimum bias cross section of $80 \pm 10$ mb based on a measurement by ATLAS 52, with an uncertainty taken to cover the difference with respect to a similar CMS measurement 53. We assess an additional 30% uncertainty in the overall rate of each process to account for remaining differences between experimental measurements and PYTHIA predictions of the rates of light mesons per minimum bias event, based on the references cited above.

The branching fractions for all vector meson decays, $V \rightarrow \chi^+\chi^-$, as a function of the $\chi$ mass are calculated using the Van Royen-Weisskopf formula 54, normalized to the PDG value of the branching fraction for $V \rightarrow e^+e^-$ 55, and rescaled appropriately for the assumed charge of the $\chi$. The branching fractions for meson Dalitz decays, e.g., $\eta' \rightarrow \chi^+\chi^-\gamma$ or $\omega \rightarrow \chi^+\chi^-\pi^0$, as well as the $\chi^+\chi^-$ invariant mass distributions in these decays are modeled as a function of the $\chi$ mass and charge using the partial width for decays into photons, e.g., $\eta' \rightarrow \gamma\gamma$ or $\omega \rightarrow \pi^0\gamma$ 56, assuming a Vector Dominance Model for the form factors.

Production cross sections of millicharged particles from different processes are summarized in Fig. 5. The possible contribution from millicharged particle production in EM showers in the CMS calorimeters generated by particles from pp collisions is not considered in this analysis.

As a function of the $\chi$ mass. For Drell-Yan the plotted cross section requires at least one of the $\chi$s to have $|\eta| < 1$.

We also generate inclusive muon events (pp $\rightarrow X \rightarrow \mu$) that are used for calibration and background studies. The same theoretical calculation used to obtain the differential cross sections of $J/\psi$ and $\psi(2S)$ from bottom hadron decays is also used to generate muons from bottom and charm hadron decays, while muons from decays in flight of pions and kaons are generated with PYTHIA8 using the Monash 2013 tune. Muons from W and Z decays are taken from MADGRAPH5, though these electroweak processes contribute only $\sim 3\%$ of the total muon flux. Finally, muons are generated using an appropriate angular distribution to simulate cosmic ray events. This angular distribution is derived by assuming a $\cos^2(\theta_{\text{zenith}})$ distribution at the surface and propagating the muons to the demonstrator using the method described in Section 5.1.

B. Detector response

Generated particles are propagated through a simplified model of the material in the CMS detector, including the magnetic field, and the 17 m of rock between the CMS cavern and the demonstrator.
Propagation is performed with fourth-order Runge-Kutta integration, incorporating the effects of the magnetic field, multiple scattering, and energy loss. Particles are propagated until 2 m before the face of the demonstrator, after which they are fed into a full GEANT4 simulation of the remaining rock, the drainage gallery where the demonstrator is located, and the demonstrator itself. Similarly, muons from cosmic ray showers are propagated from the surface of the earth to a plane 1 m above the top of the cavern. Muon interactions in the cavern walls generate showers of gamma rays and electrons that significantly contribute to the cosmic ray background. A simulated cosmic ray shower event is shown in Fig. 6.

The simulation parameters are nominally configured to be consistent with EJ-200 scintillator and existing measurements for Tyvek reflectivity and each PMT species’ quantum efficiency [61]. Overall photon propagation is handled using GEANT4’s UNIFIED optical model [62]. Photon propagation is further calibrated by measuring the effects of scintillator roughness and wrapping quality on light attenuation in the scintillator bars and matching the effect in simulation. These measurements indicated a wrapping reflectivity $R = 0.97$ and scintillator roughness $\sigma = 1\%$, typical values for Tyvek and EJ-200 [63]. A per-channel calibration is applied to each PMT quantum efficiency so that the measured $\langle N_{\text{pe}} \rangle$ values agree between data and simulation.

The electronic response is simulated using SPE waveform templates measured on a test bench with an LED. SPE templates for each GEANT4 photoelectron are added together, with appropriate arrival times, and including the individual PMT calibration described in Sec. IIII. The resulting waveform is then added to a randomly selected zero-bias data waveform to properly account for electronic noise.

C. Validation

The simulation is validated by studying beam muons as well as cosmic ray events. The absolute rate of beam muons passing through all four slabs is compared with the rate predicted from a simulated sample of muon production from heavy-flavor and electroweak decays, as well as meson decays in flight, as described in Section IV E. We measure a rate of $0.20 \pm 0.01$ muons/pb$^{-1}$, based on a sample of 7363 muons, in agreement with the prediction of $0.25 \pm 0.08$ muons/pb$^{-1}$. The dominant uncertainties in this prediction arise from the uncertainty in the $\bar{b}\bar{b}$ cross section (21%) and from the modeling of the material between the CMS IP and milliQan (25%). This last uncertainty is derived from a 7% variation in the total amount of intervening material, which is in turn due primarily to uncertainties in both the thickness and density of the rock layer. This 7% variation corresponds to a 25% uncertainty in the muon rate because of the steeply falling muon momentum distribution. This same variation is used to derive a systematic uncertainty in the predicted signal yields, though in that case the effect is much smaller because of the smaller charge of the $\chi$.

We additionally perform a comparison of the angular distribution of beam muon trajectories, in order to probe the scattering and magnetic field modeling in simulation and validate the alignment of the detector. We compare rates of muons passing through various subsets of bars that trace a range of angles through the detector. The rates of these paths in both the horizontal and vertical directions are measured to be consistent within statistical uncertainties between data and simulation.

Finally, the GEANT4 modeling is validated by comparing distributions of photoelectron counts in bars near either beam or cosmic muon trajectories. Hits are expected from electrons and gamma rays produced as the muon travels through the rock or nearby detector material. An example comparison is shown in Fig. 7. Here we show $n_{\text{pe}}$ distributions in data and simulation in events with a tagged beam muon, for bars that do not contain a pulse $n_{\text{pe}} < 750$, and are not neighboring any such bars. Contributions come primarily from electrons and gamma rays produced in scintillator material, rock, or the lead bricks. Good agreement is seen across a wide range of $n_{\text{pe}}$ levels.

V. SEARCH FOR MILLICHARGED PARTICLES

The search for millicharged particles looks for a signal with the signature of a pulse in each of the three layers
of the demonstrator. A number of sources can produce such a signature:

- Each PMT has a dark current arising from effects such as the thermal emission of electrons from the cathode. The simplest background source comes from random overlap of three such dark rate pulses. In addition, dark rate counts may overlap with two correlated pulses from another source.

- Cosmic muon showers may generate a large number of gamma rays and electrons from an interaction of one or more cosmic ray muons with the rock in the milliQan cavern. This may cause a pulse in each layer of the demonstrator. Such a background could also be expected from a beam muon that travels close to the demonstrator.

- Radiation in the cavern, scintillator bars or surrounding material can cause correlated deposits in several bars. The lead blocks placed between layers should reduce the probability of deposit in multiple layers arising from photons or electrons while the slabs provide shielding of neutrons.

- Afterpulses, which are small pulses caused by positive ions generated by the ionization of residual gases in the PMT, can appear several hundred nanoseconds to over a few microseconds after the initial pulse. The afterpulses from correlated deposits in several PMTs may overlap and produce a signal-like signature in the demonstrator. For this to occur, the interaction event that gives rise to the afterpulses must not be triggered because, in this case, the afterpulses will fall in the 125 µs readout deadtime that follows each triggered event, and will not be recorded.

Selections are applied in order to reject contributions from these background sources. If there is a pulse within the acquisition time window in any panel, or in more than one bar in each layer, the event is rejected. These requirements reject backgrounds due to cosmic muon showers, which are expected to cause deposits across the detector. In addition, if there is a pulse in any slab within the acquisition time window consistent with originating from a muon ($n_{pe} > 250$) the event is vetoed. This requirement rejects deposits due to beam and cosmic muons passing close to the bars. The bars with reconstructed pulses are required to be pointing to the CMS IP. This reduces the backgrounds from neutrons, cosmic muon showers and random overlap, while being efficient for signal, which typically has a small angular spread. To mitigate backgrounds from afterpulses, in each channel a requirement is made to reject the event if a pulse occurs before the window in which the pulse may be involved in the trigger decision. In addition, the first pulse in each channel must have the largest $n_{pe}$ value. Events that contain initial pulses in the bars with a large spread in $n_{pe}$ (maximum $n_{pe}$/minimum $n_{pe} > 10$) are vetoed to reject events containing contributions from different sources, such as dark rate overlap with shower deposits or deposits from two or more shower particles traveling through the demonstrator. Finally, the maximum calibrated time difference between the first bar pulse in each layer ($\Delta t_{\text{max}}$) is required to be less than 15 ns, which is efficient for signals traveling through the detector from the CMS IP and forms a powerful rejection of backgrounds that have different paths through the detector, such as cosmic muon showers, or that have deposits in each layer that are uncorrelated in their timing, such as dark rate overlap.

Selected events are subsequently categorized into five signal regions (SRs) through requirements on both the number of slabs that contain a pulse and the minimum $n_{pe}$ of the pulses in the three bars. This categorization allows for sensitivity to a wide range of charge values in the signal parameter space. The definitions of the five SRs are summarized in Table I. For events with a pulse in each of the three layers the selection criteria provide high efficiency for the targeted models while rejecting the background by more than five orders of magnitude.

Residual background passing selection is estimated for each signal region by measuring the pass/fail ratio of the timing requirement in events with a hit in each layer, consistent with signal requirements except that the bars do not form a pointing path towards the CMS IP, and then multiplying it by the number of events failing the timing selection that form a pointing path towards the CMS IP. This prediction method relies on the independence of the dominant backgrounds on the pointing path requirement. This method is used rather than taking the prediction from the beam-off data set as it is robust against time dependent drifts in the PMT response. However,
the beam-off data set provides a statistically independent sample to validate the prediction without contamination from signal. The results of the beam-off prediction for the SR are summarized in Table I. The uncertainty in the prediction reflects the limited statistics in the regions used to make the prediction. The prediction is shown to be in agreement with the observation for all validation regions. The level of agreement between prediction and observation in each validation region is used to derive a systematic uncertainty in the prediction.

TABLE I. Sequential impact of each requirement on the number of events passing the selection criteria.

| Selection                        | Data Beam-on | Data Beam-off | Signal \( m_\chi = 0.05 \text{ GeV} \) | Signal \( m_\chi = 1.0 \text{ GeV} \) | Signal \( m_\chi = 3.0 \text{ GeV} \) |
|---------------------------------|--------------|---------------|----------------------------------------|----------------------------------------|----------------------------------------|
| Common \( \geq 1 \) hit per layer | 2003170      | 1939900       | 136.4                                  | 34.2                                   | 5.7                                    |
| Selections                      | 714991       | 698349        | 123.1                                  | 31.0                                   | 5.0                                    |

The search is interpreted using the signal model described in Section IV. The full set of selection criteria described in Section V is applied to each event. The efficiency to pass these criteria for three benchmark \( \chi \) masses and charges is shown in Table II. The predictions are found to be consistent with the observations in all SRs. The predictions are evaluated independently for each model point and are summarized below

- Signal cross section (described in Sec. IV.A): typically 15–30% depending on the mass of the \( \chi \).

The predictions are found to be consistent with the observation for all validation regions. The level of agreement between prediction and observation in each validation region is used to derive a systematic uncertainty in the prediction.

TABLE II. Summary of the results of the validation using the beam-off data set. The systematic values are derived from the level of agreement between the prediction and observation.

| Region \( N_{\text{slab}} \) min \( n_{pe} \) | Prediction Observation Systematic |
|---------------------------------------------|----------------------------------|----------------------------------|
| 1 \( 0 \) \([2.20]\) | 121.2\(^{+6.0}_{-5.9}\) | 131 | 8% |
| 2 \( 0 \) \(> 20\) | 47.4\(^{+5.2}_{-4.8}\) | 45 | 5% |
| 3 \( 1 \) \([5.30]\) | 7.8\(^{+2.5}_{-2.0}\) | 9 | 15% |
| 4 \( 1 \) \(> 30\) | 2.7\(^{+2.1}_{-1.4}\) | 4 | 48% |
| 5 \( \geq 2 \) - | 0.8\(^{+1.4}_{-1.1}\) | 1 | 25% |

VI. INTERPRETATION
• Material interactions (described in Section IV.C): typically 1–5% depending on the charge and mass of the $\chi$.

• Pulse timing (described in Section III): typically 1–40% depending on the charge of the $\chi$.

• $\langle N_{PE} \rangle$ calibration (described in Section III): 1–50% depending on the SR populated by the $\chi$.

• Limited simulated sample size: up to 30%.

FIG. 8. Exclusion at 95% confidence level compared to existing constraints from colliders, CMS, ArgoNeuT and SLAC MilliQ [10–16, 22] as well as the indirect constraint from the CMB relativistic degrees of freedom [21].

Under the signal plus background hypothesis, a modified frequentist approach is used to determine observed upper limits at 95% confidence level on the cross section ($\sigma$) to produce a pair of $\chi$s, as a function of mass and charge. The approach uses the LHC-style profile likelihood ratio as the test statistic [64] and the CLs criterion [65, 66]. The observed upper limits are evaluated through the use of asymptotic formulae [67]. Figure 8 shows the exclusion at 95% confidence level in mass and charge of the $\chi$. The exclusion is compared to existing constraints, showing new sensitivity for $\chi$ masses above 700 MeV.

VII. FUTURE PLANS

In Refs. [25, 32] we assumed the largest irreducible background to the signal would come from dark-current pulses in the PMTs. From experience gained by operating the demonstrator, we now know that an equally important background comes from correlated effects caused by activity in the scintillator (from effects such as environmental radiation or cosmic muon showers). This realization prompted us to revisit the milliQan design, adding a fourth layer in order to mitigate the contribution from these correlated backgrounds.

We have studied the effect of adding a fourth layer with the demonstrator. The demonstrator has three rather than four layers so backgrounds are determined for three-fold coincidence and then extended to four-fold using an additional pulse in a slab. The results of this study indicate that the contribution from pure dark-current overlap drops to a negligible level for the case of four-fold coincidence, even with the somewhat high-noise PMTs that are used in the demonstrator. The calculations presented in Refs. [25, 32] remain a conservative estimate of the milliQan discovery potential since the background with four layers as measured with the demonstrator is significantly smaller than the estimate used in those simulations.

Given the experience obtained from the demonstrator, we are confident that the proposed full-scale detector will perform as expected provided sufficient funding becomes available.

VIII. CONCLUSIONS

We have deployed a prototype dedicated detector at the LHC to conduct the first search for elementary particles with charges much smaller than the electron charge at a hadron collider. We analyzed a data sample of proton-proton collisions collected at $\sqrt{s} = 13$ TeV provided by the LHC, corresponding to an integrated luminosity of 37.5 fb$^{-1}$. The existence of new particles with masses between 20 and 4700 MeV is excluded at 95% confidence level for charges varying between 0.006e and 0.3e, depending on mass. New sensitivity is achieved for masses larger than 700 MeV. The successful operation of the milliQan demonstrator and search carried out have shown the feasibility of a dedicated detector for millicharged particles at the LHC and provided important lessons for the design of the full detector.

ACKNOWLEDGMENTS

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN. In addition, we gratefully acknowledge the CMS Collaboration for supporting this endeavor by providing invaluable logistical and technical assistance. We also thank Eder Izaguirre and Itay Yavin for their enduring contributions to this idea. Finally, we acknowledge the following funding agencies who support the investigators that carried out this research in various capacities: FWO (Belgium) under the Excellence of Science EOS be.h project n. 30820817; DFG and HGF (Germany); Swiss Funding Agencies (Switzerland); STFC (United Kingdom); DOE and NSF (USA); Lebanese University (Lebanon).
