Abstract. The key to improve the photocurrent is how to promote the generation rate and reduce the recombination rate of the photo-hole pair. In this paper, a p-n heterjunction structure in Polyaniline (PANI)/ZnO nanocomposites was formed via mechanical mixing process. Compared with ZnO, PANI doped ZnO nanocomposites exhibit obviously enhanced response. It might be attributed to the p-n heterojunctions formed between p-type and n-type enhanced response, enhancing the charge separation and in turn promoting the photoconductivity of the film. The 5at-%PANI doped ZnO nanocomposites demonstrates the highest response.

1. Introduction

Heterojunction composites of conjugated polymers and semiconductor nanoparticles (NPs) have attracted a great deal of attention in photocatalysis [1], solar cells [2], gas sensors [3] and photodiodes [4]. The hybrid organic–inorganic semiconductor junctions are envisaged to complement each others’ functional advantages while overcoming their respective drawbacks. The high quality schottky junction or p-n junctions formed the composites interface have improved charge separation. [5]

Among the inorganic nanoparticles, ZnO nanomaterials have received enormous interest in exclusive electrical, catalytic, electronic and optical properties due to their wide band gap (3.3eV), low power threshold sand high exciton binding energy (~60 meV) as well as their low cost. [6] The conducting polymers, which have substantial π-electrons through the polymeric chain, are the excellent hosts for the trapping of the carriers from the semiconducting nanomaterias.[7] PANI has received much attention as a promising material for microelectronic devices due to unique electrical, optical, photoelectric properties and good environmental stability. [8] PANI is extensively used as p-type material which could be deposited by various techniques such as wet, chemical, and electrophoretic methods on n-type semiconducting electrodes for p-n heterostructure devices. [9] Various methods have been widely used for the synthesis of the nanocomposites of PANI with the inorganic nanoparticles ZnO.

The results indicate that ZnO together with PANI, an inorganic/organic hybrid structure shows a promising application in the UV photodetection. [10-11] Under the light illumination, ZnO and PANI produce photo electric-hole pair. The p-n heterointerface between ZnO and PANI can promote to reduce the recombination rate of the photo-generated electron-hole pair. Although there are many methods to prepare the composite material, the main purpose is to improve the transfer of the photo-generated electrons from

the ZnO. However, the interfacial area in the structure may accelerate recombination, suggesting the need to manage the content of ZnO or PANI.

In this work, we designed porous PANI/ZnO nanocomposites with the different mass ratios of PANI:ZnO from 0:100 to 100:0 to evaluate photoconductivity response. The photoconductivity measurement is made to test the photoelectrical response of each sample, and the best content of PANI is confirmed based on the photoconductivity. The aim of this paper is to evoke the importance of a subject that has been overlooked, as well as to establish a method to calculate the percolation threshold of p-n heterojunction nanocomposites, which is based on photoconductivity measurement. The PANI/ZnO nanocomposites have been characterized by FT-IR, UV visible spectroscopy and SEM.

2. Experimental Section

2.1 Materials

Commercial PANI (average size 1 μm) and ZnO (average size 80nm) were used. Other chemicals used in the experiment were of analytically pure grade. All of them were used as received without any pretreatment. Fixed quantity of ZnO nanoparticles were mixed with different weight of doped polyaniline powder. Six different ratios of ZnO(Z) and Polyaniline(P) were studied labeled as ZP100:0(ZP000), ZP99:1(ZP001), ZP95:5(ZP005), ZP90:10(ZP010), ZP50:50(ZP050), and ZP0:100(ZP100) were prepared with different weight ratio as indicated above.

The two pure powders and a certain amount of organic solvent (a 55:30:10:4:1 weight-% combination of terpineol, butyl carbitol, di-n-butyl phthalate, span 85, and ethyl-cellulose) were mixed in a 7:3 weight ratio. Organic solvent was used mainly as thickening agent and rheological agent for screen printing. The mass of powder in each combination was 10 g. Each sample was processed in a QM-3SP04 ball miller (Nanjing University Instrument Factory, China) for 3 hours at 250 rpm to obtain a paste suitable for screen printing. The paste was printed onto an Au interdigital electrode which was preprinted on an alumina substrate. The spacing of the fingers in the Au interdigitated electrode is 0.4mm. The dimensions of each sample were 8 mm by 6 mm by 10 μm thickness. The latter value was controlled by the screen printing machine (WJ-LCD4050CHL Shenzhen Screen-Star Instrument Co. China). These samples were heat-treated for 30 min at 200 °C to eliminate the organic solvent. After the above procedures, a thick porous film was obtained in each case. [12]

2.2 Photoconductivity Measurement

The photoconductivity of each device in the material library was measured by a homemade photoconductivity measurement platform. All the samples were located in the stainless steel test chamber and tested under different light sources (UV LED 365 nm, 36 W/m²) with constant specific bias voltage and ambient air conditions (20 °C and below 20% relative humidity) which was controlled by the dry air generator and the mass flow controller.

A typical conductivity-time curve (in this film) is shown in Figure 4. The bias voltage was added at 10s, and the dark conductivity was obtained. Illumination by LED was initiated at 20s and conductivity was monitored, reaching a maximum (at which the generation and recombination of electron-hole pairs achieves dynamic equilibrium) by 160 seconds for all samples. The LED was turned off at 180s. Finally the bias voltage was unloaded at 350s. All the photoconductivity measurements were lasted for 360s.

To obtain the I–V characteristics, current was continuously measured as function of voltage. In the light irradiation experiments, we used UV LED array (365nm, 36W/m²) and the lamp-to-sample distance was 1cm.

2.3 Characterization
The morphologies of the prepared samples were observed on field-emission scanning microscopy (FSEM, Sirion 200 FEI). Room-temperature Fourier transform infrared (FT-IR) spectra were recorded in the range of 4000 - 500 cm\(^{-1}\) on VERTEX 70 (made by Bruker Co., Germany) using the KBr pellet technique. The UV-vis DRS spectra (Lambda 35, PerkinElmer) was used to obtain the reflectance spectra of the samples over 300-800 nm.

3. Results and Discussion

3.1 Characterizations

The FT-IR spectra of the different composites are showed in Figure 1. The band at 490 cm\(^{-1}\) observed in the spectra of Figure 1 is assigned to ZnO.[13] All the characteristic bands of PANI [14], such as the C=C stretching deformation of the quinoid (1556 cm\(^{-1}\)) and benzenoid (1472 cm\(^{-1}\)) rings, the C-N stretch of secondary aromatic amines (1300 cm\(^{-1}\)), the aromatic C-H in-plane bending (1140 cm\(^{-1}\)), and the N-H stretching (3447 cm\(^{-1}\)), can be observed in Figure 1.

Figure 2 shows the UV-visible adsorption spectra of the PANI/ZnO nanocomposites and the PANI. The PANI shows sharp and a broader bands at 350 and 650 nm which are ascribed to $\pi \rightarrow \pi^*$ transitions of the benzenoid groups and $n \rightarrow \pi^*$ transitions due to polaron formation into the conducting PANI, respectively.[14] It can be clearly seen that the absorption edge of the ZnO/PANI nanocomposites could be shifted into visible spectrum. This red shift might occur due to the interaction between the hydroxyl groups of ZnO and the quinoid ring of emeraldine salt (ES) which facilitates the charge transfer from highly reactive imines groups at quinoid unit of ES to ZnO nanomaterials via partial hydrogen bonding. [15] Additionally, the relative intensity of the peaks increases with the increased weight percent ratio of PANI nanomaterials in PANI/ZnO nanocomposites. This increased intensities of the peaks might at tribute to the enhanced hydrogen bonding in the form of NH– (PANI) ·····O──Zn [16].

The SEM images of the samples are shown in Figure 3. The composite is composed of the ZnO nanoparticles with the diameter of 40–60 nm and the PANI with500 nm. From the SEM image, the size of PANI particles is larger than that of the ZnO particles. When the content of ZnO is larger than 50%, the PANI particles are surrounded by ZnO, which like as islands in ZnO.
3.2 Photoconductivity response of the PANI/ZnO nanocomposites

Figure 4 shows the photoconductivity responses of composites with the mass ratios of PANI:ZnO from 0:100 to 100:0. It is shown that the conducting polymer PANI performs the less response to UV because of the high recombination of electron and hole [16-17]. In the whole experimental range, the PANI/ZnO nanocomposites demonstrate much higher response than that of the pure ZnO, indicating that the addition of PANI is beneficial to the UV responding of the ZnO nanoparticles. Especially, the 5 at-%PANI doped ZnO nanocomposites (ZP005) exhibits markedly higher response than pure, 1, 10, 50 and 100at-%PANI-ZnO nanocomposites. It also suggests obviously the increasing photoconductivity amplitude can be seen with the increase of the PANI to ZnO from 0/100 to 5/100. When the initial ratios of PANI to ZnO larger than 5/100, the photoconductivity amplitude begins to decrease.

3.3 I-V characteristics of the PANI/ZnO nanocomposites

Figure 5 illustrates the I-V characteristics of the n-ZnO/p-PANI (ZP050 and ZP010) nanocomposites heterojunction in the dark and UV irradiation conditions at room temperature, respectively. The linear curve in the Figure 5 (a) can indicate that the ohmic contact is formed between the ZnO and PANI (ZP010). The inset on upper side in Figure 5 (a) shows no current flow in the measured voltage range, indicative the resistance of the film being very high. The two non-linear curves in Figure 5 (b) exhibit almost symmetric characteristic with an extended plateau suggestive of tunneling conduction through the PANI/ZnO nanocomposites. This result confirms that a p-n junction was successfully formed.

3.4 Mechanism analysis
The conducting polymer PANI is p-type semiconductor and can form the holes-accumulation layer in the grain boundary. [14] The metal oxide ZnO is typical n-type semiconductor and the ZnO surface can easily adsorb oxygen molecules. [18-19] The chemical adsorb oxygen molecules, which trap the free electrons from the conduction band of ZnO, can transform to negative oxygen ions. [20] So the electrons-depletion layer is formed at the grain boundary of ZnO. Based on the research of Lin et al. [10], both of the energy bands will bend up nearby the surface of the p-n heterjunction (as shown in Figure 6 (a)).

Under UV illumination, the interface of ZnO and PANI will be changed by photo-generated electrons and holes. The photo-generated holes migrate to the ZnO surface and react with the negative oxygen ions. The photo-generated electrons transfer between the LUMO of PANI and the CB of ZnO. The photo-generated holes transfer between the VB of ZnO and the HOMO of PANI. These lead to the decrease of holes-accumulation layer of PANI and the increase of the electrons-depletion layer of ZnO, which is as shown in Figure 6 (b).

Here $e^-$ and $h^+$ represent photogenerated electrons and holes, respectively. The subscript Z and P mean the related subjects stay in ZnO and PANI, respectively. During the on and off illumination test, several processes might have happened:

$$ZnO + \text{photo}(UV) \rightarrow e^{-}_Z + h^+_Z \quad (1)$$
$$PANI + \text{photo}(UV) \rightarrow e^{-}_P + h^+_P \quad (2)$$
$$e^{-}_P \rightarrow e^{-}_Z \quad (3)$$
$$h^+_Z \rightarrow h^+_P \quad (4)$$
$$e^{-}_Z + O_2 \rightarrow O_2^- \quad (5)$$
$$O_2^- + h^+_Z \rightarrow O_2 \uparrow \quad (6)$$
$$e^{-}_Z + h^+_Z \rightarrow \text{recombination(heat)} \quad (7)$$
$$e^{-}_P + h^+_P \rightarrow \text{recombination(heat)} \quad (8)$$
During illumination, \( \text{O}_2 \) reacts with photo induced holes. [20] The adsorbed oxygen molecules are released with the help of this reaction, which will lower the barrier height as proposed by Muraoka.[20]

### 4. Conclusion

A facile, simple and environment friendly mechanical mixing process method was used to synthesise PANI doped ZnO p-n heterojunction nanocomposites. Compared with pure ZnO nanoparticles, PANI doped ZnO p-n heterojunction samples demonstrate enhanced UV responding performances. It might be ascribed to the formation of p–n heterojunctions between p-type PANI and n-type ZnO interfaces, further promoting the generation rate and reducing the recombination rate of the photo-generated electron-hole pair. Among all fabricated samples, the 5at-% PANI doped ZnO nanocomposites demonstrate the highest responses in the UV light. All experiments indicate the 5at-% PANI doped ZnO p-n heterojunction nanocomposites as a promising sensing candidate for UV detection in practical application. The PANI is like some islands that store holes from the VB of the ZnO. This island-structure is helpful to separate electron-hole pairs.
