Abstract

We investigate the effect of directed short and long range connections in a simple model of small world network. Our model is such that we can determine many quantities of interest by an exact analytical method. We calculate the function $V(T)$, defined as the number of sites affected up to time $T$ when a naive spreading process starts in the network. As opposed to shortcuts, the presence of un-favorable bonds has a negative effect on this quantity. Hence the spreading process may not be able to affect all the network. We define and calculate a quantity named the average size of accessible world in our model. The interplay of shortcuts, and un-favorable bonds on the small world properties is studied.

†Electronic address: vahid@sharif.edu
Real life networks, whether made by nature, (e.g. neural, metabolic and ecological networks), or made by human (e.g. the World Wide Web, power grids, transport networks and social networks of relations between individuals or institutes), have special features which is a blend of those of regular networks on the one hand and completely random ones on the other hand. To study any process in these networks, (the spreading of an epidemic in human society, a virus in the internet, or an electrical power failure in a large city, to name only a few), an understanding of their topological and connectivity properties is essential (for a review see and references therein). Recently obtained data from many real networks show that like random networks, they have low diameter, and like regular networks, they have high clustering. Since the pioneering work of Watts and Strogatz, these networks have attracted a lot of attentions and have been studied from various directions.

In contrast to most of the models studied so far, many real networks like the World Wide Web, neural, power grids, metabolic and ecological networks have directed one-way links. These types of networks may have significant differences in both their static and dynamic properties with the Watts-Strogatz (WS) model and its variations. The presence of directed links affects strongly many of the properties of a network. For example, for the same pattern of shortcuts, the average shortest path in an directed network is longer than that in an undirected one, due to the presence of bonds with the wrong directions (blocks) in many paths. So is the spreading time of any dynamic effect on the lattice. Consider the quantity $V(T)$ defined as the average number of sites which are visited at least once when we start a naive spreading process at a site and continue it for $T$ steps. Note that we mean an average over an ensemble of networks and initially infected sites and by the naive spreading process we mean that at each step of the spreading process all the neighbors of an infected site are equally infected. The quantity $V(T)$ may be taken as a crude approximation for the number of people who have been infected by a contiguous disease after $T$ time steps has elapsed since the first person has been infected. Clearly this is a simplification of the real phenomena, since in real world a disease may not affect an immunized person or may not transmit with certainty in a contact. However as a first approximation, $V(T)$ may give a sensible measure of the effect in the whole network. Since in an directed
network, an effect only spreads to those neighbors into which there are correctly directed links, there will be pronounced differences in this important quantity between an directed and an undirected network. As a concrete example consider a ring with \( N \) sites, without any shortcuts, where to emphasize the absence of shortcuts, we denote \( V(T) \) by \( V_0(T) \). If all the links have the same direction, we have \( V_0(T) = T \), and if all of them are bidirectional, we have \( V_0(T) = 2T \). In both cases the whole lattice gets infected after a finite time. However if the links are randomly directed then \( V_0(T) \) may be much lower and furthermore, there is a finite probability that only a small fraction of the whole lattice gets infected.

Adding shortcuts to this ring of course has a positive effect on the spreading. In a sense we have a chance to see the interplay of two different concepts of small worlds in these networks. The size of the world as a whole may be small due to the ease of communication with the remote points provided by long range connections, however the world accessible to an individual may be small due to the absence of properly directed links to connect it to the outside world.

It is therefore natural to ask how the presence of directed links and (or) directed shortcuts affects quantitatively the small world properties of a network? How we can make a simple model of a small world network with such random directions? A WS-type model for these networks may be as shown in figure (1). However due to their complexity, these networks should usually be studied by numerical or simulation methods and they seldom amend themselves to exact analytical treatment.

A. The aim, structure and results of this paper

As we will show in this paper, with slight simplification one can introduce simpler models which although retain most of the small world features, are still amenable to analytical treatment. This is what we are trying to do in this paper. In this paper we introduce one such model following our earlier work [23] which was in turn inspired by the work of [24]. The basic simplifying feature of these networks is that all the shortcuts are made via a central site, figure (2). For such a network many of the small world quantities, can be calculated exactly. In particular, once \( V(T) \) defined above is calculated, many other quantities like the average shortest path between two sites can be obtained. An exact calculation of \( V(T) \) is however difficult for the case where both the shortcuts and the links have random directions.
We therefore proceed in two steps to separate the effects of randomness in the two types of connections. First, in section 2, we remove the shortcuts and calculate exactly $V(T)$ for a ring with random links, figure (3). To emphasize the absence of shortcuts we denote this quantity by $V_0(T)$. Note that $V_0(T)$ depends only on the structure of the underlying ring and its short-range connections. Then in section 3, we consider only the effects of randomly directed shortcuts, that is we let directions of the links on the ring to be regular and fixed say clockwise, and calculate exactly $V(T)$, where again for emphasis on the shortcuts we
denote this quantity by $S(T)$.

We then argue, in section 4 that in the scaling limit where the number of sites goes to infinity with the number of shortcuts kept finite, most of the spreading takes place via the links and only from time to time it propagates to remote points via the shortcuts. In this limit it is plausible to suggest a form for $V(T)$ which takes into account the effect of both the random links and the shortcuts in the form $V(T) = S(V_0(T))$. This may not be an exact relation but as we will see it will give a fairly good approximation of $V(T)$, as shown by the agreement of our analytical results and the results of simulations. This then means that in more complicated networks, one can separate the effects of short and long range connections and superimpose their effect in a suitable way. We conclude the paper with a discussion.

II. EXACT CALCULATION OF $V_0(T)$ IN A RING WITH RANDOM BONDS

Consider a regular ring of $N$ sites whose bonds are directed randomly. Each link may be directed clockwise with probability $r$, counterclockwise with probability $\ell$, and bidirectional with probability $1 - r - \ell$.

Thus we have a problem similar to bond percolation in a small world network. Suppose that at time $T = 0$ site number 1 is infected with a virus. We ask the following questions:

After $T$ seconds how many sites have been infected on the average? What is the average speed of propagation of this decease in the network? These questions have obvious answers
for rings with regularly directed or bi-directional bonds, namely the number of infected sites are respectively $T$ and $2T$, with corresponding speeds of propagation being 1 and 2. In the randomly directed network, the situation is different. For example if both neighbors of site 1 are directed into this site, this site can not affect any other site of the network. Such a site being effectively isolated has an accessible world [18] of zero size (figure3). To proceed with exact calculation, consider the right hand side of site 1. The probability that exactly $k < T$ extra sites to the right have been infected is $P_+(k) := (1 - \ell)^k \ell$, and the probability that exactly $T$ extra sites have been infected is $P_+(T) := (1 - \ell)^T T$. Therefore the average number of extra sites infected to the right of the original site is

$$V_0^+(T) = \sum_{k=1}^{T} kP_+(k) = T(1 - \ell)^T + \sum_{k=0}^{T-1} k(1 - \ell)^k \ell = T(1 - \ell)^T + \frac{1}{\ell}[1 - \ell + (1 - \ell)^T(\ell - 1 - \ell T)].$$ (1)

Going to the large $N$ limit where,

$$N \to \infty, \quad \ell \to 0 \quad \mu := \ell N, \quad t := \frac{T}{N}, \quad v_+(t) := \frac{V_0^+(T)}{N}$$ (2)

we find the simple result

$$v_0^+(t) = \frac{1}{\mu}(1 - e^{-\mu t})$$ (3)

The same type of reasoning gives the number of sites infected to the left $v_0^-(t)$ and thus the total number of infected sites will be:

$$v_0(t) = \frac{1}{\mu}(1 - e^{-\mu t}) + \frac{1}{\lambda}(1 - e^{-\lambda t})$$ (4)

where $\lambda := rN$. What are the meaning of the scaled variables? The parameter $\mu$ is the total number of sparse blocked sites in the way of propagation to the right, with a similar meaning for $\lambda$. $v_0(t)$ is the fraction of infected sites up to time $t$. In a bidirectional lattice, all the sites could be infected after the passage of $T = \frac{N}{2}$ seconds, or at $t = \frac{1}{2}$ and if $t$ passes $\frac{1}{2}$, some of the sites become doubly visited. Therefore it is plausible for the sake of comparison to define a quantity in our ring, namely the average size of the accessible world $\nu_0^{acc} := v_0(\frac{1}{2})$, which turns out to be:

$$v_0^{acc} = \frac{1}{\mu}(1 - e^{-\frac{\mu}{2}}) + \frac{1}{\lambda}(1 - e^{-\frac{\lambda}{2}})$$ (5)

It is seen that the presence of only a small number of blocked bonds causes a significant drop in the average size of this accessible world. For example a value of $\lambda = \mu = 4$ leads to
$v_0^{acc} \sim 0.4$. The long range connections (shortcuts) make the world small with the ease of communication they provide, however blockades make the world small in this new sense. The speed of propagation is found from

$$\dot{v}_0(t) = e^{-\mu t} + e^{-\lambda t}. \quad (6)$$

In the symmetric case where $\lambda = \mu$, equation (6) simplifies to:

$$v_0(t) = \frac{2}{\mu} (1 - e^{-\mu t}) \quad (7)$$

with

$$\dot{v}_0(t) = 2e^{-\mu t} \quad (8)$$

Note that at the early stages of spreading when $\mu t \ll 1$, and the effects of blocked bonds has not yet been experienced, the infection propagates with speed equal to 2 as in a regular network. The effect of blocking comes into play when $t$ becomes comparable to $\frac{1}{\mu}$.

As a few number of shortcuts may enhance the speed of propagation, a few number of blocked bonds may have the opposing effect. First the blocks reduce the speed of propagation as is clear from (6) and second and more importantly they reduce the number of accessible sites, or the size of accessible world. It will thus be of interest to see how these two effects compete in a random network where there are both shortcuts and blocks. We will study this in the final section of this paper. To this end we first study the effect of directed shortcuts in an otherwise regular ring with no blocks.

### III. THE LONG RANGE CONNECTIONS

In this section we are to consider only the effect of randomly directed shortcuts in the spreading process and obtain exactly the function $S(T)$ for this network, figure [4]. Note that this function has the same meaning as $V(T)$, except that for emphasis on the role of shortcuts in it we have adopted a new name for it. We fix a regular clockwise ring. Between a site and the center there is a shortcut going into the center with probability $p$ and out of the center with probability $q$. The site remains unconnected to the center with probability $1 - p - q$. The average number of connections into and out of the center are respectively $M_i := Np$ and $M_o := Nq$.

Consider sites 1 and $j$. We want to find the probability that the shortest path between
these two sites be of length $l$, a probability which we denote by $P(1, j; l)$. A typical shortest path of length $l$ connecting these two nodes is shown in figure (4), where the first inward connection to the center occurs at site $i$ and the last outward connection from the center occurs at site $j + i - l$. Such a path occurs with probability $(1 - p)^{i-1}pq(1 - q)^{l-i}$. Summing over all such configurations gives us the probability for the shortest path between sites 1 and $j$ to be of length $l$. For $l \neq j - 1$, we have:

$$p(1, j; l \neq j - 1) = \sum_{i=1}^{l} (1 - p)^{i-1}pq(1 - q)^{l-i} = pq\left[\frac{(1 - p)^{l}}{q - p} + \frac{(1 - q)^{l}}{p - q}\right],$$

and $p(1, j; j - 1)$ is determined from normalization:

$$P(1, j; j - 1) = 1 - \sum_{i=1}^{j-2} P(1, j; l) = \frac{1}{p - q}\left(p(1 - q)^{j-1} - q(1 - p)^{j-1}\right).$$

Note that $p(1, j; l \neq j - 1)$ does not depend on $j$, a property which is true for standard small world networks.

Now consider a naive spreading process starting at site 1. The number of sites affected up to time $T$, denoted by $S(T)$, builds up in two ways, via the links on the ring and via the shortcuts. The first way gives a contribution $T + 1$ and the second way gives a contribution $(N - T - 1)\sum_{l=1}^{T} p(1, j; l)$ where $(N - T - 1)$ is the number of sites beyond direct reach at time $T$ which has been multiplied by the probability of any of these sites being at a distance shorter than $T$ to site 1 via a shortcut. Putting this together we find:
\[ S(T) = T + 1 + (N - T - 1) \sum_{l=1}^{T} P(1, j; l) \]
\[ = N + (N - T - 1) \left[ \frac{q}{p-q} (1-p)^{T+1} + \frac{p}{q-p} (1-q)^{T+1} \right] \]

In the scaling limit where \( N \to \infty \), \( p, q \to 0 \), where \( M_i \) and \( M_o \) are kept fixed and \( s(t) := \frac{S(T)}{N} \), we find:

\[ s(t) = 1 - \frac{1 - t}{M_i - M_o} \left( M_i e^{-M_i t} - M_o e^{-M_o t} \right) \]

In the symmetric case where \( M_i = M_o = M \) this equation simplifies to:

\[ s(t) = 1 - (1 - t)(1 + Mt)e^{-Mt} \]

with the speed of propagation

\[ \dot{s}(t) = e^{-Mt}(1 + Mt + M^2 t - M^2 t^2) \]

Figure (5) shows the speed of propagation as a function of time for several values of \( M \).

IV. THE SPREADING EFFECT IN A DIRECTED SMALL WORLD NETWORK

We now come to the problem of composing both the blocks and the shortcuts in a model of small world network. That is we consider the ring of figure (2) where randomly directed
shortcuts are added to a ring with randomly directed links. We can not obtain exact expressions for this network from first principle probability considerations. However we can obtain expressions for $v(t)$ in the scaling limit by a heuristic argument and compare our results with those of simulations. Consider equation (13). This equation shows how the presence of $2M$ randomly directed shortcuts in a regular clockwise ring affects the spreading effect. On the other hand we know that the number of sites infected up to time $t$ in the absence of shortcuts, has changed to $v_0(t)$. Due to the rarity of shortcuts compared to the regular bonds, most of the spreading takes place via the local bonds, the role of shortcuts is just to make multiple spreading processes happen in different regions of the network. This role is the same whatever the underlying lattice is, and therefore for a general network, at least in the scaling regime, we can assume that equation (13) can be elevated to $v(t) = s(v_0(t))$, i.e;

$$v(t) = 1 - (1 - v_0(t))(1 + M v_0(t)) e^{-M v_0(t)}.$$  

(15)

For a fully random network where $2M$ randomly directed shortcuts are distributed on a ring with already random links, we assume that this relation holds true with $v_0(t)$ taken from (4). This suggestion may not provide an exact solution for the network, however we think it provides a fairly good approximation. In fact exact solution for the case where all the links on the ring are bidirectional is possible and it confirms the above ansatz, that is we obtain an exact expression only by setting $v_0(t) = 2t$ in the above formula. Moreover this separation of the effect of short and long range connections may be also useful in more complicated networks. Whether this assumption is plausible or not can be checked by comparison with simulations. The results of simulations are compared with those of equations (4) and (12) in figure (6) and (7).

V. STATIC PROPERTIES

Once the functions $V(T)$ or $v(t)$ are obtained, the static properties of the network i.e., the average shortest path between two arbitrary sites and its probability distribution can be calculated directly.

Since $V(T)$ by definition is the number of sites whose shortest distance to site 1 is less than or equal to $T$, we find the number of sites whose shortest distance is exactly $T$ to
FIG. 6: $V(T)$ for a fully random network in the case $N = 5000, r = 0.02, l = 0$. Analytic results (lines) versus simulations (symbols) which have been averaged over 1000 realizations of the network.

FIG. 7: $V(T)$ for a fully random network in the case $N = 5000, r = l = 0.005$. Analytic results (lines) versus simulations (symbols).

be $V(T) - V(T - 1)$. Since site 1 is an arbitrary site, we find the probability distribution of the shortest distance between two arbitrary sites which are accessible to each other as:

$$P(T) = \frac{V(T) - V(T - 1)}{V_{\text{acc}}}$$

where $V_{\text{acc}}$ is the average size of the accessible world. (There is of course a slight approximation here in that we are taking averages of the denominator and numerator separately.)

For a regular ring with shortcuts, $V_{\text{acc}} = N$, since all the sites are accessible. We will discuss the case of random rings in the sequel. In the scaling regime the above formulas transform
to:

\[ P(t) = \dot{v}(t). \]  

Note that \( P(t) \) is normalized, i.e. \( \int_0^1 P(t) dt = v(1) - v(0) = 1 \). The average shortest path for the network of figure (11) when \( M_i = M_o = M \), turns out to be:

\[ \langle t \rangle = \frac{1}{M^2}(2M - 3 + (M + 3)e^{-M}) \]  

This is in accord with the result of [24]. This formula shows that the presence of a small number of shortcuts, causes a significant drop in the average shortest path from 1 to very small values. In this sense the world gets smaller by long range connections.

We now study the static effects of random directed bonds on a ring without shortcuts. The presence of blocks makes the world small in a different sense, namely for each site the number of accessible sites gets smaller. In fact the average size of the world accessible to a site is not \( N \) anymore but it is given by \( V(\frac{T}{2}) \) (see the paragraph leading to equation (5)). Hence the probability of shortest paths is given by \( P(T) := \frac{V(T) - V(T-1)}{V(\frac{T}{2})} \), or in the scaling limit by

\[ P(t) := \frac{\dot{v}(t)}{v(\frac{t}{2})} \]  

This probability is normalized, i.e. \( \int_0^\frac{1}{2} P(t) dt = 1 \). We obtain from (18)

\[ \langle t \rangle = \frac{1}{v(\frac{t}{2})} \int_0^\frac{1}{2} t \dot{v}(t) dt \]  

However in order to assess the situation in this network, we should compare the average shortest path with the size of this small world itself, namely we should calculate \( \frac{\langle t \rangle}{v_0^{\text{acc}}} \). Inserting equation (17) into (19) we find:

\[ \frac{\langle t \rangle}{v_0^{\text{acc}}} = \frac{2 - (\mu + 2)e^{-\frac{\mu}{2}}}{4(1 - e^{-\frac{\mu}{2}})^2} \]  

Figure (8) shows both the average size of the accessible world \( v_0^{\text{acc}} \) and the ratio \( \frac{\langle t \rangle}{v_0^{\text{acc}}} \) of the average shortest path to the size of accessible world as a function of the number of blocks \( \mu \). It is seen that for \( \mu = 0 \), when there is no block, the size is 1 and the average of the shortest path is \( \frac{1}{4} \) as it should be. With a few number of blocks the size drops dramatically and the average of shortest path within the world increases. Note that with increasing \( \mu \) the average shortest path increases to its maximum value of \( \frac{1}{2} \).

For the fully random network, we use equations (15) and (18) to obtain the average of shortest path. The result is shown in figure (9) for several values of the parameters.
FIG. 8: The average size of accessible world and the average shortest path for a regular ring with randomly directed bonds without shortcuts.

FIG. 9: The average shortest path for a fully random network.

VI. CONCLUSION

We have studied the effect of directed short and long range connections in a simple model of small world network. In our models all the shortcuts pass via a central site in the network. This makes possible an almost exact calculation of many of the properties of the network. We have calculated the function $V(T)$, defined as the number of sites affected up to time $T$ when a naive spreading process starts in the network. As opposed to shortcuts, the presence of un-favorable bonds has a negative effect on this quantity. Hence the spreading process may be able to affect only a fraction of the total sites of the network. We have
defined this fraction to be the average size of the accessible world in our model and have calculated it exactly for our model. We have studied also the interplay of shortcuts, and un-favorable bonds on the small world properties like the size of accessible world, the speed of propagation of a spreading process, and the average shortest path between two arbitrary sites. Our results show that one can separately take into account the effect of randomness in the directions of shortcuts and the short-range connections in the underlying lattice and at the end super-impose the two effects in a suitable way. We expect that this will hold also in more complicated lattices of small world networks.
