Abstract
Background: Encephalopathy is an uncommon but serious presentation of lead toxicity. Objective: We aimed to determine and follow-up the brain magnetic resonance imaging (MRI) abnormalities in the patients with lead encephalopathy due to ingestion of lead-contaminated opium. Methods: In a cross-sectional study during lead-contaminated opium outbreak, all lead-poisoned patients with any signs/symptoms of encephalopathy were included. Results: Of 19 patients with lead encephalopathy, five died early and other five could not be sent to MRI during their hospitalization period. Mean age was 51 ± 11 years and males were dominant (89%). Median IQR blood lead level was 101 (81, 108) µg/dL (range: 50 to 200 µg/dL). There was no correlation between MRI findings and signs/symptoms. MRI was normal in six and abnormal in three. Bilateral symmetric involvement of all lobes was observed. Gray matter, gray-white matter junction, and subcortical white matter were also affected. Follow-up MRI was performed in two with abnormal MRI which showed complete and near complete resolution of the abnormalities after cessation of opium use and treatment. Conclusion: There was no correlation between MRI findings and BLL. Complete recovery of brain MRI lesions was detected after cessation of opium use.

Background
Encephalopathy is an uncommon but serious presentation of lead toxicity [1]. Lead encephalopathy is generally described by sudden commence of the manifestations including severe headache, vomiting, convulsions, mental aberration and excitement [2]. Although blood lead levels (BLLs) of higher than 100 µg/dL generally accompany with lead encephalopathy, much lower levels (as low as 38 µg/dL) may also result in encephalopathy in chronic toxicities [1]. During an outbreak in Iran, almost 3800 opium users were evaluated at Loghman-Hakim Hospital, and found to have high BLLs. Lead-contaminated opium was considered as the source of oral contamination [3-5]. Lead-contaminated opium has been recently discussed in the literature [6]. The objective of the current report was to determine the magnetic resonance imaging (MRI) characteristics of lead encephalopathy due to ingestion of lead-contaminated opium. We also would like to perform a follow-up MRI after treatment in these patients to see if treatment improved their MRI abnormalities.

Methods
2.1. **Study design and setting**

This cross-sectional study was carried out during an outbreak of lead toxicity due to lead-contaminated opium in Tehran between September 2016 and August 2017 with a BLL range of 47.3–1124 μg/dL in a sample of 80 patients [3]. All data was pooled from a referral center for poisoned patients with annual admissions of almost 24000 intoxicated patients supposed to be the biggest in-patient clinical toxicology center of the world [7].

2.2. **Selection of participants**

All lead-poisoned patients who referred with any signs/symptoms of encephalopathy including loss of consciousness or seizure were considered as the potential participants [3]. Diagnosis of lead toxicity was made based on BLLs higher than normal (normal range;<10 μg/dL) checked by atomic absorption technique (*Graphite Furnace Atomic Absorption Spectrometry* [GFAAS]). After termination of treatment, BLL was followed using Lead Care II device.

Our MRI unit has recently been established with no supporting ventilator for comatose patients. Therefore, only patients who were stable and not intubated could be sent for MRI. If a comatose intubated patient improved and could be extubated, he/she would also be considered to be transferred to MRI unit where MRI was performed at the earliest convenient time. Bedside electroencephalogram (EEG) was done based on the treating physician’s decision.

Our primary outcome was MRI findings of the patients with lead encephalopathy while determination of the demographic characteristics of the patients and follow-up results of the abnormal MRIs were the secondary outcomes. **MRI was performed using Vantage Elan 1.5T MR system (Toshiba Medical Systems Corporation [TMSC]).**

2.3. **Statistical Analysis**

For the description of quantitative variables with normal and non-normal distribution, mean (±SD) and median [IQR interquartile range] were used, respectively. For qualitative variables, percent of frequency was used. To compare normal/abnormal MRI findings with categorical variables, Fisher’s exact test was applied. For comparing continuous variables with normal/abnormal MRI findings, t-test or Mann-Whitney U test was used. A *P* value less than 0.05 was considered to be statistically
significant. Statistical package for social sciences (SPSS) version 17.0 (SPSS Inc., Chicago, Ill, USA) was used for analysis.

Our institutional ethics committee approved this study.

Results
Almost 3800 lead-poisoned opium user patients were admitted to our center [3]. Of the 19 patients who were eligible to be entered nine were not intubated and could be sent for MRI. Five died early and MRI was out of service for another five patients. Lab tests for other medications/toxins that could affect brain MRI (including carbon monoxide, methanol, pesticides, cyanide, and sympathomimetics) were negative. Hypoxic encephalopathy was also excluded. Table 1 shows epidemiological characteristics of the patients.

Their mean age was 51±11 years (range; 39 to 72) and males were dominant (89%). Median [IQR] blood lead level was 101 [81, 108] µg/dL (range; 50 to 200) with a mean hemoglobin level of 9.2±1.7 mg/dL (range; 7.6 to 12.8).

EEG was performed in three and was normal in one and abnormal in two of those who had MRIs (Table 1).

MRI was normal in six cases (67%) and showed pathologic changes in three cases (Figures 1-3). There was no statistically significant difference between those with and without MRI abnormalities in terms of BLL, hemoglobin level, age and clinical manifestations.

Figures 1-3 show MRI findings of three patients during hospitalization. On follow-up, all patients became symptom-free after quitting the lead-contaminated opium and initiation of treatment. Two, out of three patients with abnormal MRI accepted to undergo the follow-up MRI. The time interval between the two MRIs was three and twelve months in cases 3 and 1, respectively. MRI findings resolved with no major neurological damage. BLLs were 8 and 25 µg/dL on follow-up evaluations of these two patients, respectively. We could not find any correlation between MRI findings and BLLs, age, Hb, EEG, and signs/symptoms.

Discussion
MRI findings of lead encephalopathy due to regular ingestion of opium have not been reported to
date. In our study, three patients (33.3%) showed abnormal MRI findings. Atre and colleagues reported bilateral symmetric involvement of the parasagittal occipital, temporal, parietal and frontal lobes and a right cerebellar lesion. In the first patient of our study, the lesions dramatically resolved without chelation therapy. This may emphasize on the importance of cessation of lead exposure as the most effective treatment in lead encephalopathy [8].

Lead encephalopathy is usually associated with BLLs higher than 100 μg/dL; but, there are few reports of encephalopathy with levels even lower than 70 μg/dL [9]. The minimum BLL in our study was 50 μg/dL and encephalopathy due to such low BLL might be due to the chronic nature of the toxicity.

Bilateral symmetric involvement of the thalami and lentiform nuclei were reported in two patients with abnormal signal in external capsule and subcortical white matter in one patient [10]. Bilateral thalamic and T2-weighted high signal areas in the basal ganglia, posterior thalamus, pons, insula, and periventricular white matter have also been reported [9, 11]. In our patients, bilateral symmetric involvement of occipital, parietal and to a less extent, frontal and temporal lobes were observed. Gray matter, gray-white matter junction, and subcortical white matter were also affected.

Our patients’ imaging results are similar to regular findings in posterior reversible encephalopathy syndrome (PRES) which is an acute neurotoxic state characterized by temporary neurological symptoms including acute headache, altered mental status, visual loss, and coma. PRES is mainly due to hypertension but other conditions including immunosuppression therapy, hypercalcemia, and chronic renal/hepatic failure can also lead to it [12].

Interestingly, organic lead is able to cross blood-brain barrier, accumulate in the brain tissue, and mimic or mobilize calcium ions. The consequence would be apoptosis following excessive influx of calcium that could lead to death. “Leaky microvessels” following endothelial dysfunction in lead excitotoxicity and PRES have the same MRI findings [13].

The data obtained in the study, although limited by the number of patients, is interesting because the patients’ encephalopathy improved after discontinuation of the contaminated opium. Response to treatment ruled out other opioid-related complications such as “chasing the dragon” or hypoxic
encephalopathy in our patients.

Conclusions

One-thirds of our encephalopathy patients, that could be retrieved for follow-up MRI, had reversible abnormal MRI findings. MRIs of the more severely poisoned patients would have been worse, but as these patients did not undergo MRIs, this cannot be known. With the knowledge on our limited cases, no correlation exists between the MRI findings and BLLs or clinical signs. Substitution of lead on calcium channels in CNS can mimic hypercalcemia and subsequent PRES-like imaging.

Declarations

**Ethics approval and consent to participate:** This study approved by Shahid Beheshti University of Medical Sciences ethics committee (IR.SBMU.RETECH.REC.1396.74). The informed consent from was waved due to retrospective nature of the study by ethics committee.

**Consent to publish:** Available.

**Availability of data and materials:** The data is all presented in the text.

**Competing interests:** None.

**Funding:** This study was supported by Social Determinants of Health Research Center, Shahid Beheshti University of Medical sciences, Tehran, Iran (Grant no. 10307).

**Authors' Contributions:** HHM is the guarantor of integrity of the entire study. MHM and MS gave the study concepts and designed the study. NZ, and MHM did the literature research. MHM and HHM performed the data and statistical analysis. NZ prepared the manuscript draft and HHM did edit the final manuscript. All authors have read and approved the manuscript.

**Acknowledgements:** None

Figures
On admission MRI: MRI shows bilateral symmetric involvement of two areas in parasagittal parietal lobes. Gray matter, gray white matter junction, and the subcortical white matter are involved. The lesions are bright on T2-weighted and FLAIR images and hypointense on T1-weighted images. No evidence of diffusion restriction is noted. Faint nodular and gyral enhancement is seen in the mentioned areas. Follow-up MRI: Lesions completely resolved on the repeat MRI without chelation therapy.
Admission MRI: MRI shows symmetric involvement of the occipital, parietal, and frontal lobes in the parasagittal region. Gray matter, gray white matter junction, and subcortical white matter are affected. The lesions were bright on T2-weighted and FLAIR images and hypointense on T1-weighted images. Mild to moderate edema is associated with these lesions. No evidence of diffusion restriction is noted in mentioned areas. Follow-up MRI: Near complete recovery of the lesions are seen in the repeat MRI after chelation therapy.
Admission MRI: MRI shows symmetric involvement of the parasagittal areas of bilateral parietal and occipital lobes. Asymmetric involvement of bilateral posterior temporal lobes is also evident. The affected areas are gray matter, gray white matter junction, and subcortical white matter. The lesions signal on T2-weighted and FLAIR sequences are high and low on T1-weighted sequence. No evidence of Diffusion restriction is depicted in involved areas. This patient refused follow-up MRI after chelation therapy as he believed to be completely fine.
